phases of experimental procedures together. First, following an explanatory overview of the session, they completed a series of questionnaires that provided an evaluation of their preinjection physical and affective state. Then they took specious "pre-vitamin-injection" vision tests and had a baseline heart rate measurement while performing visual tasks. Next a physician administered the injection (alleged to at least subtly affect visual activity), with accompanying information regarding expected side effects. During a 15-minute waiting period, supposedly before the drug would begin to take effect, the confederate engaged in a prearranged sequence of euphoric activities. At the end of the waiting period, measures of self-reported affect, experienced symptoms, and an evaluation of the confederate were obtained. The specious "drug condition" vision tests were then readministered in keeping with the purported rationale of the study. The physician and the experimenter then examined and interviewed each subject, who was dismissed only when his pulse and blood pressure were normal and there were no manifest signs of arousal. The duration of each session was about 90 minutes. Finally, a separate and thorough debriefing session was held for all subjects at the completion of the study.

Subjects

The subjects were 85 male undergraduates attending Stanford University. They were initially recruited by means of a notice asking for males over 18 years of age to join the "Stanford Subject Pool for Drug Research." The medical records of these subjects (maintained at the student health center) were examined by a physician. Subjects were excluded from the subject pool if they met any of several criteria that were contraindicative of a normal-range reaction to epinephrine or that might indicate a prior history of epinephrine use (e.g., asthma, a respiratory condition, high blood pressure) or if currently using medication. Fifteen volunteers were thus judged ineligible to participate.

Subjects were individually contacted by phone and invited to participate in a study "being conducted by a member of the ophthalmology department concerning the influences of an injection of a vitamin supplement on visual activity." A standard medical interview was conducted over the phone, both as a further screening device and to lend credence to the cover story (several additional volunteers were eliminated through this second phase of screening.) The eligible volunteers were then randomly preassigned to one of six experimental conditions, which are described subsequently.

Procedure

In keeping with the purported medical nature of the study, the experiment was performed in the student health center, where appropriate signs directed the incoming subjects to the "vision testing area." The subject and a male experimental confederate of comparable age went through all of the procedures together. At the beginning of the session, the experimenter presented an overview of the experiment to them. He repeated the description of the study as an ophthalmology experiment dealing with vitamins and visual activity and described the tandem procedures for the repeated vision tests and "physiological monitoring." Subjects were told that the physician would administer the vitamin injection following the completion of the initial series of tests. The injection was described as having no major side effects, although the experimenter indicated that some minor, transitory effects had been reported by some previous subjects. Misinformation was given regarding these somatic effects; instead of the usual epinephrine sequelae, subjects were led to expect dryness of the throat, slight headache, and some slight coolness in toes and fingers. Subjects were told that they would have to wait about 15 minutes after the injection before the vitamin would be affecting the appropriate visual structures, and then they would proceed with the second series of eye tests, physiological recordings, and questionnaires.

After the experimenter delivered this overview, the first set of questionnaires was administered. These contained self-ratings concerning vision, physical condition, and current affective state. When the forms were completed, the participants proceeded to the "baseline testing" phase of the experiment. The vision tests consisted of reading a standard eye chart with and without a pair of field-inverting goggles and taking the Speed of Color Discrimination Test (Messick, 1964). The "preliminary physiological monitoring" period, which included several visual tasks, initiated the continuous recording of the subject's heart rate as he proceeded through the rest of the experiment. Silver disk surface electrodes were attached to the center of the subject's upper and lower sternum. These were then connected to a small radio transmitter (Narco Bio-Systems, FM1100-E) placed on the back of the subject's shoulder. The transmitter was described to the subject as a "relay box" that was connected to the polygraph (E & M Physiograph) immediately behind him. In actuality, the signal from the transmitter was picked up by two FM receivers (Narco Bio-Systems, FM1100-6). One was connected to the polygraph in the vicinity of the subject; the other was connected to a polygraph (Beckman Type R dynagraph with a 9806-AC coupler and a 9857 cardiotachometer coupler) concealed from view in another room.

After the subject performed several "eye movement" tasks, a 1-minute resting baseline measure of heart rate was obtained. As the subject's "initial physiological monitoring" period was being completed, the physician entered the room and pretended to administer an injection to the confederate, who had just completed his baseline vision testing. The experimenter conspicuously disconnected the "relay box" from the adjacent polygraph and informed the subject that no further physiological recording would be done until the second part of the experiment.

actuality, the subject's heart rate information was being continuously telemetered by the radio transmitter to the receiver and polygraph in the other room.

Manipulation of physiological arousal. After the physician finished with the confederate, he entered the physiological recording area where the subject was waiting. As the physician prepared to give the injection, he repeated both its earlier description as a "multicomponent vitamin supplement called D-27" and the earlier statement regarding its likely somatic effects. The injection was then administered subcutaneously to the subject's upper right arm. Subjects in the epinephrine-basic group received an injection of .5cc epinephrine (a 1:1000 solution of Parke-Davis Adrenalin). The placebo-basic group received a .5-cc injection of bacteriostatic water. Only the physician (a cardiologist) was aware of the contents of specific injections. The experimenter then escorted the subject to the adjacent waiting area, where the confederate was already seated at a table. The rationale for the 15-minute waiting period was restated. After instructing the two participants simply to make themselves comfortable, the experimenter excused himself and left them alone in the room.

Manipulation of social environment. The confederate enacted a carefully rehearsed sequence of behaviors that was closely patterned on the behavior of the "euphoric" accomplice in the Schachter and Singer (1962) study. The confederate had been instructed to be friendly and responsive to the subject but to maintain a primarily independent role.

The programmed "euphoric" script of the confederate, both verbal and nonverbal, followed this approximate chronology (which began within a minute after the subject's injection):

1. *Minutes 1 through 3.* Looks around, examines materials on the table, sketches or doodles, hums.

2. *Minutes 4 through 5.* Crumples paper into a ball, tosses it at wastepaper can; repeats with a couple more sheets of paper; gets up, retrieves misses, tries different types of shots from different positions; tosses one to the subject, inviting him to try a shot.

3. *Minutes 6 through 8.* Sits down again, picks up a piece of paper, makes a paper airplane and flies it; makes another one, flies it; retrieves plane from the floor and flies it in the direction of subject; repeats flying plane.

4. *Minute 9.* Notices and tries a swivel-type foot exerciser on the floor.

5. *Minutes 10 through 12.* Picks up paper airplane, sits down and plays with materials on the table; makes a slingshot with a rubber band; tears off a piece of the airplane to use as "ammunition" and shoots it at a clock on the far wall; while retrieving shot, notices old, empty folders on a piece of equipment and sets them up as a target; makes more "ammunition" and continues to shoot at the target.

6. *Minutes 13 through 15.* While picking up "ammunition" from floor, notices hula hoops against the wall behind some exercise equipment (in the adjoining physical therapy room), picks one up and tries a couple of times to rotate it freely around his hips, and then spins it across the room toward the subject; continues spinning the hoop on the floor until the sound of a door opening indicates the experimenter's imminent return; replaces hoop and returns to his seat.

When the experimenter reentered, he stated that as soon as the second set of questionnaires was completed, the participants would proceed with the physiological monitoring and vision tests "under vitamin conditions." These questionnaires were the same as the first series but also included both a checklist and ratings of a variety of experienced physical symptoms. An additional form asked both participants for a rating of their experimental partner. The purpose of this "partner evaluation" (really a check on the perceived mood of the confederate and also of suspicion as to his role) was rationalized as necessary to match subjects for a future phase of the study. When the questionnaires had been completed, the initial vision tests and tasks were repeated. Following this, the subject was brought to another room where the physician checked his pulse rate and blood pressure. The experimenter gave a brief exposition about the experiment, paid the subject, and requested that he not discuss the experiment. A complete debriefing session was postponed for several weeks until all of the subjects had been tested. At these subsequent sessions subjects filled out a modified form of the Autonomic Perception Questionnaire (Mandler, Mandler, & Uviller, 1958) and were then completely debriefed.

Experimental Conditions

Sixteen subjects were randomly assigned to each of the two basic experimental conditions. The epinephrine-basic group received the epinephrine injection, while the placebo-basic group received the placebo injection. In all other respects the procedure outlined above was identical for both conditions. Four other groups (with 12 subjects in each) were utilized to provide essential comparative data. In the epinephrine – neutral confederate condition, the confederate did not behave euphorically, but instead he was merely passively pleasant. In the placebo – arousal symptoms group, the information regarding anticipated consequences of the injection was changed to that appropriate for epinephrine. The final two groups represented an attempt to strengthen the manipulation of physiological arousal. In the epinephrine – increased arousal group, the dosage of the epinephrine injection was individually adjusted for the subject's body weight. In the epinephrine – increased salience group, subjects not only received the adjusted dosage but also engaged in activities that were designed to increase the salience of their arousal.

Epinephrine – neutral confederate group. In this condition every aspect of the procedure, with the exception of the confederate's behavior, was identical to that for the subjects in the epinephrine-basic group. The confederate, instead of acting in a eu-

phoric manner, offered no dramatic cues as to his emotional state. When the subject and confederate were brought together in the waiting room after the injection, the confederate casually removed a paperback book from his back pocket and proceeded to read it for the entire waiting period. He responded in a friendly, pleasant manner to any questions that were asked, but then returned to his reading.

The primary reason for this neutral confederate condition was to provide a comparison level for assessing the extent of affect induction elicited by the euphoric confederate in epinephrine-injected subjects. The neutral confederate condition permits a direct evaluation of the impact of varied social environments, holding inadequately explained physiological arousal constant.

Placebo – arousal symptoms group. In this condition, a group of placebo subjects was told that the symptoms expected from the injection included those actually appropriate to an injection of epinephrine. This information was provided during the overview at the beginning of the session and again just prior to the injection. Subjects in the placebo – arousal symptoms group were told, "You may notice that your hand will start to shake, your heart will start to pound, and your face may get warm and flushed." With the exception of this change in symptom expectation, the procedures for this group were identical to those for the placebo-basic group.

The primary reason for this experimental condition was to further examine the effects of the symptom-expectancy manipulation. This is the particular information Schachter and Singer (1962) employed to provide some subjects in epinephrine-injection conditions with an "adequate" explanation for their ensuing physiological arousal. The arousal symptoms group illustrates the effects of providing arousal-appropriate information, independent of the subsequent induced state of physiological arousal. In particular, we wanted to test the possibility that telling subjects to expect their heart to pound and so forth might have independent, direct effects on affect in addition to simply providing a possible explanation for any subsequent experience of physiological arousal.

Heightened arousal groups. In these conditions, instead of receiving a "fixed" dosage of epinephrine, subjects received dosages in proportion to their body weight. The average body weight of the subjects in the epinephrine-basic group was approximately 72 kg; thus, the standard injection of .5 cc represents an average injection of about .007 cc/kg. Heavier-weight subjects in the constant dosage condition, of course, received relatively smaller dosages than lighter ones.

The 12 subjects randomly assigned to the epinephrine – increased arousal treatment received an injection of .01 cc of epinephrine per kilogram of body weight. The individual dosages ranged from .55 cc to .82 cc ($M = .72$ cc; $SD = .08$). With the exception of this change in dose determination, the procedures and manipulations for this group were identical to those for the epinephrine-basic group.

This method of selecting dose levels controls for any differential effects resulting from individual differences in body weight. The average of the actual doses administered to this group is equivalent to 1.44 times the fixed dosage administered in the other epinephrine conditions and in the Schachter and Singer study. As such, this method also represents a somewhat stronger level of the physiological arousal manipulation for the group as a whole.

The 12 subjects randomly assigned to the epinephrine – increased salience condition were also administered the body-weight-adjusted drug dosage of .01 cc/kg. Individual dosages ranged from .64 cc to .93 cc ($M = .77$ cc; $SD = .08$). In addition, for these subjects the postinjection waiting period, while euphoric in tone, was designed to increase the salience of the induced physiological arousal. The subject and confederate spent the first 5 minutes of the waiting period writing a story about a Thematic Apperception Test (TAT) picture (to increase the salience of hand tremor). The remaining 10 minutes were spent sitting with their eyes closed (to focus attention on increased palpitations and changes in respiration). The confederate enacted his "euphoric" role both verbally and nonverbally. He joked, hummed, and gave various indications of being happy.

This change in task demands during exposure to a "euphoric" confederate, combined with the somewhat stronger arousal manipulation resulting from the weight-adjusted drug dosages, provided conditions under which the awareness of physiological arousal should have been enhanced. The critical components were still present: arousal that was inadequately explained and a generally euphoric confederate.

Dependent Measures

Physiological, behavioral, and self-report responses were measured.

Physiological measures. Each subject's heart rate was monitored continuously using a cardiotachometer. The three measurement periods were (a) baseline—the 1-minute relaxation period during the initial physiological monitoring; (b) preinjection—the 1-minute period immediately preceding the injection; and (c) waiting period—the period beginning at 1 minute after the injection and lasting until the end of the waiting period. For scoring purposes, the rate indicated by the cardiotachometer record was read at 10-sec intervals for each of the appropriate periods. Means where then calculated for the appropriate epochs.

Behavioral measures. During the waiting period, the subject was both observed and videotaped through a one-way mirror. Each discrete occurrence of smiling or of laughter was recorded on an event recorder (Esterline-Angus). The total frequency of each of these behaviors was determined for each subject. A composite index of positive emotional expression was calculated by weighting the number of smiles by one and the number of laughs by two and then summing these scores. The videotape of each

subject's activities was scored by an observer who was blind to the experimental condition. The type, frequency, and duration of the subject's various activities, as well as their temporal occurrence with respect to the confederate's actions, were noted. Our scoring procedure was based on a weighting of type of activity, following Schachter and Singer (1962, p. 391). Thus, 5 points were given for hula hooping, 4 for shooting with the slingshot, 3 for paper airplanes, 2 for paper basketballs, 1 for doodling, and 0 for doing nothing. Scores for amount of "imitation" (follows confederate's lead) and "initiation" (innovates new activities or encourages further participation of confederate) were also determined. To assess the reliability of these various measures, 10 of the videotapes were selected at random and rated by a second independent observer. The scores for both judges of the total frequency for each activity for each of the 10 subjects differed by only 1 unit or less 97% of the time and were in complete agreement 85% of the time. The imitation and initiation scores were in exact agreement 90% and 70% of the time, respectively; and for both categories the scores were within 1 point of each other 100% of the time.

Self-report responses. Questionnaires were used to assess the following: (a) the subject's description of his affective state, (b) his perception of physiological arousal, and (c) his evaluation of the confederate. The measures concerning affective state were administered both at the beginning of the experiment and following the waiting period. The reports of physical state and the confederate evaluations were obtained only after the waiting period. In order to disguise the actual focus of the questionnaires, several "dummy" questions were included (such as ratings of hunger, thirst, and degree of alertness, as well as ratings of different aspects of visual activity). The questionnaires also contained several open-ended questions encouraging the subject to comment on various aspects of his experience.

Two of the affect self-report items provided the major dependent measure for purposes of replication of the previous findings by Schachter and Singer (1962): "How irritated, angry, or annoyed would you say you feel at present?" and "How good or happy would you say you feel at present?" Subjects checked one of five response alternatives: 0 (not at all), 1 (a little), 2 (quite), 3 (very), and 4 (extremely). An additional series of 11 items sampled a broader affective domain. These were in the form of bipolar adjective pairs, with the subject rating himself on a 7-point scale ranging from −3 for one adjective to +3 for the other. Anxious–calm, elated–depressed, and angry–peaceful are examples of these 11 item pairs.

The questionnaires also contained two sections pertaining to the subject's perception of various physical symptoms. The experience of palpitations and the feeling of tremor were rated on the following scale: 0 (not at all), 1 (a slight amount), 2 (a moderate amount), and 3 (an intense amount). The subject also completed a checklist noting the presence or absence of a variety of symptoms, such as heart beating faster, breathing faster, numbness, and watery eyes.

The subject rated the confederate on a scale from −3 to +3 for each of nine adjective pairs (e.g., friendly–unfriendly, relaxed–agitated). One pair, happy–sad, permitted a direct check on the adequacy of the confederate's portrayal of a "euphoric" mood.

An additional questionnaire was administered at the debriefing session. This questionnaire was developed from the Autonomic Perception Questionnaire and was used to measure the extent to which a subject experienced specific physical symptoms with different states of affect. The standard deviations of symptom ratings were used to derive an affect symptom–discrimination index. Subjects with a low index score did not report experiencing symptoms that varied with the different emotions (e.g., if a subject rated himself as "perspiring a great deal" regardless of the specific emotion, that symptom would have a standard deviation of zero). Subjects with a high index score, on the other hand, did report experiencing different symptoms with different emotions.

Results

Five subjects met an a priori exclusion criterion based on skepticism of the validity of the confederate's role (three subjects from placebo and two from epinephrine groups). Exclusion resulted when a subject noted himself as "suspicious" on the adjective checklist and questioned the credibility of the confederate on the open-ended questionnaire items. These subjects were replaced with additional subjects from the available subject pool.

This study was conducted in two phases: First, the basic epinephrine and placebo groups, both paired with a euphoric confederate, were tested; a week later, testing of the four additional groups began. All subjects came from the same population, were tested within a comparable time period, and were randomly assigned to experimental conditions. For purposes of data analysis, the six groups are treated as if they had been tested contemporaneously.

Checks on the Manipulations

The manipulations appear to have been effective in creating the conditions necessary to evaluate the hypotheses under consideration. Heart rate increases as a function of the injection were found only for the epinephrine – heightened arousal groups, in both

Table 1
Reported Experience of Physiological Symptoms

Measure	Placebo groups		Epinephrine groups			
	Basic	Arousal symptoms	Basic	Neutral confederate	Increased arousal	Increased salience
Mean degree of tremor	.1	.2	1.6	1.5	1.6	1.7
Mean degree of palpitations	.1	.2	.9	.9	1.4	1.6
Mean number of epinephrine symptoms	.5	.8	2.8	2.4	3.4	3.4

of which the dosage of epinephrine had been individually adjusted for body weight. The injections of epinephrine, however, clearly did lead subjects to perceive more symptoms of physiological arousal than were perceived by placebo subjects. The confederate was perceived as being happy and euphoric in all experimental conditions where he behaved that way and as significantly less so where he enacted an affectively neutral role. Finally, the misinformation regarding the symptoms associated with the injection was reflected in the failure of a majority of the subjects to mention the injection as a possible explanation for their feeling state.

Physiological arousal. Because of apparatus problems, only 68% of the sample had complete physiological records. Examination of the change in heart rate from the period immediately preceding the injection to the average heart rate during the 15-minute waiting period revealed the following results. There were no significant changes in heart rate for the two epinephrine conditions given the standard, fixed dosage of .5 cc of epinephrine: $M = -2.3$ beats per minute (bpm) for the epinephrine-basic group, and $M = +.9$ bpm for the epinephrine – neutral confederate group. There were, however, increases in heart rate for the two heightened arousal conditions. The mean increase for the epinephrine – increased arousal group was +6.7 bpm, $t(7) = 3.12$, $p < .02$, while the mean increase for the epinephrine – increased salience group was +6.0 bpm, $t(8) = 2.26$, $p < .10$. The placebo-basic group did not show a significant change in heart rate ($M = -3.0$ bpm), while the placebo – arousal symptoms group had a significant decrease in heart rate ($M = -6.7$ bpm), $t(8) = 2.54$, $p < .05$.

Perceived arousal symptoms. Table 1 presents the mean ratings of palpitation and of tremor. Four of the items on the symptom checklist ("moist, sweaty palms," "heart is beating faster," "stomach feels upset," and "breathing is faster") were considered as indicative of epinephrine – induced arousal, and their mean frequency is also reported in Table 1. Subjects in the two placebo groups rarely reported tremor and palpitations, and only occasionally did they report experiencing one of the epinephrine symptoms. In contrast, the subjects in the four epinephrine conditions on the average reported experiencing slight to moderate amounts of tremor and palpitations, as well as at least several of the epinephrine symptoms. Thus, with respect to reports of both the degree of tremor and palpitation and also to reports of the number of symptoms experienced, the injection of epinephrine did definitely produce discernible symptoms of arousal that were not found with the placebo injection.

Confederate's affective state. The success of the "social cognition" manipulation was determined from the ratings of the confederate completed by each subject after the waiting period. The means of the ratings in each of the five groups paired with a euphoric confederate indicate that he was indeed perceived as being happy. On a scale from +3 (happy) to −3 (sad), the confederate was given mean ratings that ranged from +1.5 to +2.2 for the five conditions having a euphoric confederate. When tested against a neutral score of zero, each of these mean ratings is highly significant ($p < .001$). This perception of the confederate as being happy was even found in the ratings of the more restrained confederate in the epinephrine – in-

creased salience condition ($M = +1.7$). In contrast, the epinephrine group with the affectively "neutral" confederate gave him a mean rating of +.7 (not significantly different from the neutral midpoint of zero).

Explanation of symptoms. The subjects were misinformed regarding the possible symptoms associated with the injection. Following Schachter and Singer's (1962) procedure, subjects were subsequently categorized as "self-informed" or "not self-informed" about the source of their physiological arousal. Subjects who mentioned something about the injection (e.g., "suspect that it's the vitamin influence"; "the shot"), when asked to explain their feeling state on the final questionnaire, were classified as "self-informed." Those who made no reference to the injection (e.g., "test situation"; "the guy I was waiting with") were classified as "not self-informed." There were indeed subjects in each group who met the "self-informed" criterion. In the epinephrine conditions, this varied from 25% of the basic group and 17% of the increased arousal group to 42% of the neutral confederate group and 50% of the increased salience group, both of whom were exposed to a relatively inactive and less distracting confederate. In the placebo conditions, 12% of the subjects in the basic group and 8% of the arousal symptoms group also met the criterion. The reports in these latter groups suggest that at least some of the references to the injection in the epinephrine groups may have occurred independently of induced physiological arousal. Although the misinformation regarding likely side effects did not necessarily forestall cognitions linking the injection with subsequent feeling states, the majority of subjects did not offer such an explanation in spite of the obvious contiguity of the injection. This supports the apparent face validity of the subjects' not having a readily available "adequate" explanation for any ensuing physiological arousal.

Experimental Comparisons

The epinephrine-basic subjects did *not* express more positive affect (on either the behavioral or the self-report measures) than did the placebo-basic group. In fact, what few differences did exist between the two conditions were in the opposite direction of more positive affect for the placebo group. Heightening the arousal did not increase reports or displays of positive affect, but instead produced signs of more negative affect. For subjects with inadequately explained physiological arousal, it seemed to make little difference if they were in the presence of an affectively positive or neutral confederate. Placebo subjects given information to expect symptoms appropriate to epinephrine evidenced a negative affective bias prior to the actual injection.

Preinjection. With the exception of the information regarding possible somatic effects, the experimental procedures were identical for all subjects prior to the injection. Subjects in the placebo – arousal symptoms group were told to expect epinephrine-appropriate symptoms; subjects in the other groups were told to expect only minor, transitory symptoms (unrelated to predominant epinephrine effects). An index of general affect was derived from the set of 11 bipolar affect-adjective scales by combining the ratings on the items such that a higher score represented more positive affect in general. The placebo – arousal symptoms group was the only one that did not have a positive index score significantly different from zero (all other ps at least $<.02$). The a priori comparison of the mean for the placebo – arousal symptoms group ($M = 2.5$) with the average of the scores for the other groups ($M = 7.4$) indicates that these subjects had a significantly lower or less positive index score ($MS_w = 55.59$), $t(74) = 2.12$, $p < .05$, after being informed about possible symptoms.

The effect of the symptom-information manipulation was also assessed by the a priori comparison of the change in heart rate for the placebo – arousal symptoms group in anticipation of the injection ($M = 14.8$ bpm) with the average of the change in heart rate for the other five groups ($M = 6.4$ bpm). This comparison indicates that subjects in the arousal symptoms condition had a significantly greater increase in heart rate in anticipation of their injection than did the other subjects who had been told to expect only minor, transitory symptoms ($MS_w = 46.70$), $t(47) = 3.40$, $p < .01$. This and the general affect index demonstrate that the two de-

Table 2
Self-Report Ratings of Experienced Affect

Measure	Experimental condition					
	Placebo–basic (n = 16)	Epi–basic (n = 16)	Epi–increased arousal (n = 12)	Epi–increased salience (n = 12)	Epi–neutral confederate (n = 12)	Placebo–arousal symptoms (n = 12)
Schachter–Singer index post score[a]	1.5	1.4	.9	1.1	1.2	1.5
"Adjusted" pre–post change score[b]	+.40*	+.28	+.03	−.07	−.25	+.39
General affect index post score[a]	10.4	7.4	1.8	.5	8.2	8.3
"Adjusted" pre–post change score[b]	+3.64*	+.19	−4.31*	−6.41**	−1.00	+4.20*

Note. Epi = epinephrine.
[a] The higher the score, the more positive the reported affect.
[b] A positive score indicates a positive change in affect over time; a negative score indicates a negative change. Scores were adjusted by regression for any differences in initial values.
* $p < .05$.
** $p < .01$.

scriptions of side effects were not equivalent and that the symptom-information manipulation produced effects *prior* to the injection.

Self-report of affect. One of the self-report measures of experienced affect was identical to that employed by Schachter and Singer (1962): Subjects rated how "good or happy" and how "irritated, angry, or annoyed" they felt. Following Schachter and Singer's procedure, the "angry" score was subtracted from the "happy" score to yield a single index of affect. As can be seen in Table 2, all of the six conditions had a positive postscore on this affect index. This measure was administered both before and after the experimental manipulations in order to assess changes in reports of affect. An analysis of these changes ("adjusted" by regression on the initial scores) revealed *no* significant changes for any of the epinephrine conditions. However, the placebo-basic group showed a positive change, $t(15) = 2.20$, $p < .05$, and the placebo–arousal symptoms group also tended to do so, $t(11) = 1.86$, $p < .10$.

The other self-report measure of experienced affect was the general affect index derived from the set of 11 bipolar affect-adjective scales. Table 2 presents the mean scores on this index for the different groups. A positive general index score (significantly different from the neutral midpoint of zero) was obtained by both the epinephrine-basic group, $t(15) = 3.73$, $p < .01$, and the placebo-basic group, $t(15) = 6.40$, $p < .001$. Similarly positive scores were also obtained by the placebo–arousal symptoms group, $t(11) = 7.13$, $p < .001$, and the epinephrine–neutral confederate group, $t(11) = 2.92$, $p < .02$. In contrast, the two epinephrine–heightened arousal groups had scores that did not differ from zero.

The general index score of the epinephrine-basic group was slightly *less* positive than that of the placebo-basic group (contrary to the Schachter and Singer prediction), and that of the epinephrine–increased arousal group was significantly less positive ($p < .01$). In the epinephrine conditions, there was no significant difference between the basic and neutral confederate groups, while the scores of both of the heightened arousal groups were significantly less positive than that for the basic group (p at least $< .05$).

An examination of the pre- to postexperimental changes in general index scores ("adjusted" by regression) reveals an interesting pattern (see Table 2). In the epinephrine conditions, both the basic and neutral confederate groups showed no significant change on this affect index. However, both of the heightened

arousal groups had significantly *negative* changes on this index: for the increased arousal group, $t(11) = 2.39$, $p < .05$; for the increased salience group, $t(11) = 3.56$, $p < .01$. In contrast to all of the epinephrine groups, the two placebo conditions showed a significantly *positive* change in this general index: for the basic group, $t(15) = 2.34$, $p < .05$; for the arousal symptoms group, $t(11) = 2.28$, $p < .05$.

A comparison of the epinephrine-basic group with the placebo-basic group reveals *no* significant difference between their general index change scores. The epinephrine–increased arousal condition had significantly more *negative* change scores than the placebo-basic group ($p < .01$). In the epinephrine conditions, the change scores for the increased salience group were significantly more negative than that for the basic group ($p < .01$), and those for the increased arousal group also tended to be more negative ($p < .10$). There was no significant difference between the epinephrine-basic group and the neutral confederate group.

Emotional behavior. The analysis of the subjects' euphoric activities is restricted to the four groups in which the subjects spent the experimental waiting period with an active, euphoric confederate who went through the standardized Schachter–Singer (1962) routine. One behavioral measure of affect involved nonverbal expressions of positive affect. The numbers of observed smiles and laughs were combined to form an index of positive emotional expression. Subjects paired with the neutral confederate expressed very little positive affect ($M = 1.3$), while all the other subjects who were paired with a euphoric confederate displayed considerably more positive emotional reactions. The placebo groups had the highest scores on this index ($M = 28.1$ for the basic group; $M = 22.5$ for the arousal symptoms group). The mean score for the epinephrine-basic group ($M = 21.7$), although lower, did not differ significantly from the placebo-basic condition. However, the scores for the epinephrine–increased arousal group ($M = 18.2$) were significantly lower ($p < .05$) than those of the placebo-basic group.

Table 3
Behavioral Measures of Euphoric Activity

Measure	Experimental condition: Placebo–basic ($n = 15$)	Epi–basic ($n = 11$)	Epi–increased arousal ($n = 12$)	Placebo–arousal symptoms ($n = 11$)
Euphoric activity	35.0	25.6	14.5	19.8
Imitation	1.4	1.2	1.0	1.3
Initiation	.8	.9	.5	.5

Note. Epi = epinephrine. Higher numbers reflect greater degrees of activity. The videotapes for some subjects were not of scorable quality.

Similar to Schachter and Singer's procedure, the number of times each of the activities was performed by a subject was multiplied by the weight assigned to the presumed euphoric quality of that activity. All of these scores were then combined into an overall euphoric activity index (see Table 3). There was a considerable range of scores within each of the groups (the smallest intragroup range was 53.0), with some subjects remaining relatively inactive and others performing a great deal of euphoric behavior. The placebo-basic group had the highest score on this index—as opposed to either of the epinephrine groups. While their scores did not differ significantly from those of the epinephrine-basic group, they tended to be significantly higher than the activity scores for the epinephrine–increased arousal group ($p < .10$). The difference between the two epinephrine conditions did not approach significance. The number of different activities (i.e., the range of euphoric behavior) in which the subject engaged was also examined. Each subject was classified as either (a) participating in none or only one activity or (b) participating in more than one activity. The percentage of subjects in the second category was 67% for the placebo-basic group, 55% for the placebo–arousal symptoms group, 45% for the epinephrine-basic group, and 33% for the epinephrine–increased arousal group. The difference between the placebo-basic and epinephrine-basic groups was not significant, while the epinephrine–increased arousal

group had a significantly lower percentage of subjects exhibiting a range of euphoric behaviors than the placebo-basic group ($z = 1.76, p < .05$).

Similar to the Schachter and Singer (1962) procedure, the number of confederate activities that a subject performed after the confederate had done so was used to constitute an imitation score, and the number of innovative euphoric behaviors performed by the subject was used as his initiation score. As can be seen in Table 3, all of the experimental groups both imitated and initiated euphoric behavior. There were no significant differences between groups on either of these measures.

Additional analyses. As noted earlier, if subjects cited receiving an injection as a possible cause for their feeling state, they were categorized as "self-informed." Being self-informed, according to Schachter and Singer, should render subjects functionally unsusceptible to the affect manipulations. Consequently, their reactions should differ from cohorts not so self-informed. To test the significance of this variable on the pattern of results in the present study, t tests were performed between self-informed and not self-informed subjects on each of the dependent measures. There was no trend nor even tendency for differences between them on any of the self-report or behavioral measures of affect (all p values $> .10$). In other words, subjects responded similarly to the affect manipulations, regardless of their attributions regarding the injection.

The subjects' responses to the physiological arousal manipulation may have been influenced by their perceived association of particular symptoms with different states of affect. Correlations between the affect self-report scores and three scores derived from the subsequently administered Autonomic Perception Questionnaire (APQ) were computed. The APQ scores included the affect symptom-discrimination index (i.e., the extent to which the subject reported experiencing different symptoms with different emotions) and the standard deviation for the ratings on the specific item regarding experiencing "increased heart beat." The final APQ score was the mean on an item assessing how "bothered" the subject was by these "bodily reactions." For the placebo subjects, there were no significant correlations between the APQ scores and the self-reports of affect. However, for comparable subjects who had received an injection of epinephrine, there was a consistent pattern of significant ($p < .05$) negative correlations (ranging from $-.67$ to $-.49$) between affect reported in the experimental setting and the affect symptom-discrimination index and also the other APQ scores. The subjects who reported more negative responses to their experimentally induced, inadequately explained physiological arousal were also those who were more likely to report doing the following: (a) discriminating between different states of affect in terms of physical symptoms, (b) experiencing increased heart beat differentially with various emotions, and (c) being bothered by these bodily reactions. Thus, symptom-sensitive subjects showed a negative affective bias in response to symptoms associated with the epinephrine-induced physiological arousal.

Discussion and Conclusions

There is no evidence in the data generated by this study to warrant acceptance of the Schachter and Singer (1962) reported demonstration of the interaction of cognitive and physiological determinants of emotion. In particular, there was no instance in which subjects with inadequately explained epinephrine-produced arousal were significantly more susceptible than placebo controls to the induction of affect by exposure to a confederate who modeled euphoric behavior. If, as Schachter (1971) has suggested, the disguised injection of epinephrine actually did create "a bodily state 'in search of' an appropriate cognition" (p. 33), the majority of these subjects did not discover that cognition in the mood displayed by the euphoric confederate. Whatever arousal treatment differences did exist were likely to suggest more positive affect in this situation for placebo subjects than for epinephrine subjects.

The particular physiological substrate induced by exogenous epinephrine seems, from the consistent pattern of our data, to have

produced a relatively negative affective bias, even given the presence of a euphoric confederate. This finding became more evident under conditions of increased arousal and increased salience of the arousal. The presence of a euphoric confederate exerted some functional control over the "emotional" behaviors of the subjects, but had minimal impact on their self-reported affect. "It's like being at a party," one epinephrine subject later reported, "when everyone is clearly having a good time and you have a headache or feel depressed for some unknown reason. You don't want to rain on their parade; you might even laugh and try to join in, but you don't really feel happy." Nowhere was there evidence of inadequately explained epinephrine-produced arousal enhancing affective susceptibility to situational influences.

Reappraisal of the Schachter and Singer Conclusions

As previously mentioned, Schachter and Singer (1962) similarly found no significant differences between their placebo controls and epinephrine aroused groups (see their Table 2, p. 390). However, they considered the direction of the differences to provide "tentative but consistent" support for their predictions regarding cognitively steered physiological arousal. Their actual conclusions concerning the role of physiological arousal, however, are primarily based on several somewhat questionable post hoc internal analyses, such as classifying placebo subjects with no change in pulse as being "aroused" (see Marshall, 1976, for a fuller critique). By these means, they were able to obtain some "predicted" effects within groups on the behavioral measures. They were still unable, however, to demonstrate similar effects on the self-report measures. In the present study, procedural improvements were introduced to strengthen the possibility of finding any between-group arousal treatment effects. Despite this, there were still no significant differences obtained between the arousal treatment conditions. Opposite to what Schachter and Singer found, this time the direction of differences that did exist was in the favor of more positive affect in the presence of a euphoric confederate for the placebo group. Furthermore, this pattern of results was supported by the data from additional comparison groups. These data suggest a negative affective bias for epinephrine-produced arousal. Thus, it seems most accurate to conclude that inadequately explained epinephrine-produced physiological arousal does not enhance general affective susceptibility to environmental influences.

This lack of "emotional plasticity" is also suggested by other results in the Schachter and Singer study. Interestingly, Schachter and Singer do not compare the effects of the different social environments presented in their study. When such a comparison is done, it is apparent that the difference in reported affect between epinephrine-ignorant (without an adequate explanation) subjects exposed to an angry confederate and those exposed to a euphoric confederate is rather small (.4 scale units) compared to the difference found for epinephrine-informed (with an adequate explanation) subjects (.9 scale units). This marginal situational effect for inadequately explained physiological arousal is similar to the minimal influence found for the affective tone of the social environment in the present study. Thus, there is additional evidence to support the conclusion that inadequately explained epinephrine-produced physiological arousal does not enhance general affective susceptibility to environmental influences.

Although they only employed postexperimental measures, Schachter and Singer interpreted their within-confederate condition results in terms of *changes* in affect for their unexplained arousal groups. In the present study, the use of pre- and postexperimental measures permitted a direct assessment of actual change. No significant change in affect was found for subjects who were comparable to Schachter and Singer's unexplained arousal group. This suggests the possibility that the group differences they obtained were actually due to changes by their accurately informed epinephrine subjects. As already pointed out, this condition was the one to show the greatest situational effect. Additional evidence suggesting that the accurate information condition was the one to have the changes in affect is provided by the re-

sults in the present study for the placebo subjects who were told to expect epinephrine-type symptoms (the "accurate" information manipulation).

Placebo subjects who were told to expect the somatic effects associated with epinephrine reported relatively more negative affect prior to the injection and had a relatively greater increase in heart rate in anticipation of the injection. This information about possible effects of the injection seems to have produced a negative affective response by itself. This response appears to have dissipated over the course of the experiment, presumably because the anticipated effects did not occur (since in fact they received an injection of a placebo). If these subjects had indeed received an epinephrine injection, then it is probable their initial negative reaction would have persisted over the course of the contact with the confederate. That condition is, of course, the epinephrine – informed treatment in the Schachter and Singer study. Therefore, it seems likely that their "accurate information" manipulation, instead of precluding any affective change, actually produced one. If the differences found by Schachter and Singer are actually due to changes for their informed condition instead of their unexplained condition, then their posited motivated search to account for inadequately explained arousal is not demonstrated by their results.

Schachter and Singer (1962) have clearly made valuable theoretical contributions to our understanding of emotion. However, there does not appear to be an adequate evidential basis for the conclusions they have drawn. The conclusions suggested by the present study also seem to question the body of literature on the cognitive alteration of feeling states (see London & Nisbett, 1974), which was largely based on the Schachter and Singer work. We recognize, of course, the power of cognitions to control a range of human reactions (Zimbardo, 1969), as is also evidenced by the results of the current placebo group with arousal expectations. We equally believe, however, that there are definite limitations to the power of cognitive control. We argue for a much greater complexity in the interaction of physiological substrate and cognitive cues in determining emotions. Immediately available social cognitions are but one of many sources of information used to give arousal an emotional quality. When other determinants of various classes of responses are not explicitly acknowledged in research designs but still exert an influence, their presence is manifested in excessive error variance. Thus, many of the studies that followed in the wake of the Schachter and Singer study have failed to find predicted effects across both behavioral and experiential variables (see Bem, 1974). Or, as in the case of the extention of Schachter's theorizing to the cognitive manipulation of pain (Nisbett & Schachter, 1966), the statistically significant effects are conceptually insignificant. In that study, for example, no differences were found on any of three measures between subjects who attributed their high degree of fear to a pill or to an impending shock. The only reliable result is the least interesting one, namely, low-fear subjects who accurately attributed their arousal to the shock had a lower tolerance threshold than all other groups (none of which differed among themselves).

Inadequately Explained Arousal

The idea of dissociating physiological from cognitive elements of emotion had been suggested to Schachter and Singer by the earlier work of Marañon (1924). Marañon, it will be recalled, reported two types of reaction to epinephrine injections: "true" emotions and "cold" or "as if" emotions. In the former, not only were there the same somatic elements as in the mock emotions but also the "psychic element." It is interesting to note that the true emotions, though less frequent, were typically of a negative affective tone. A true emotion appeared spontaneously in only some cases; "in other cases, to bring it about the investigator must suggest a memory of great affective energy or force" (p. 307).

Later research (Cantril & Hunt, 1932; Landis & Hunt, 1932) confirmed Marañon's finding. In these and subsequent studies, when cases of "true" emotion were judged to be present, the emotion was generally de-

scribed as "fear," "anguish," or "anxiety." Reviews of this literature offer various explanations. Breggin (1964) suggests that the appearance of these negative emotions may have been due to the superimposed stress of the experimental procedures. A more interesting possibility is that these true negative emotions "arose from the particular (learned) associations the somatic sensations may have" (Rothballer, 1959, p. 511). These associations, in turn, are likely to have arisen from prior experiences with endogenous epinephrine. In the present study, the results indicate that subjects who reported distinguishing between emotions in terms of somatic sensations also reported more negative affect in response to their epinephrine-induced physiological arousal. We know from the reviews of the extensive research on endogenous epinephrine that "increased epinephrine excretion seems to occur in states of anxiety or in threatening situations of uncertain or unpredictable nature in which active coping behavior may be required but has not been achieved" (Schildkraut & Kety, 1967, p. 23).

The physiological substrate associated with at least a certain degree of epinephrine also seems to be somewhat uniquely associated with negative affect. Parenthetically, it is interesting to note that the incidence of subjects being "self-informed" in the Schachter and Singer study varied with the social environment. It was greater with the apparently dissimilar euphoric confederate (32%) than with the clearly negative angry confederate (13%); here the incidence was almost identical with the rate obtained for placebo subjects in the present study (12%). This finding suggests that the confederate's bizarre angry behavior provided a sufficiently plausible explanation for the subject's own negatively toned experience of arousal symptoms. It is likely, of course, that there are certain critical thresholds that must be reached before epinephrine, whether endogenous or exogenous, is associated with negative affect. In the present study, the procedures of both increasing the arousal (by taking individual differences in body weight into account) and additionally increasing its salience consistently produced indications of more negative affect. The variance in the literature in the reports of affect associated with epinephrine may be partially accounted for by individual differences in pharmacokinetics, such as rates of absorption, distribution, and metabolism (Lasagna & Laties, 1959; Smith & Rawlins, 1973), which would contribute to determining whether a threshold had been reached.

The general picture that emerges from the present study, the companion study by Maslach (1979), and a reexamination of the Schachter and Singer (1962) study indicates that epinephrine-related physiological arousal does not provide "emotional plasticity," but rather shows a consistent association with negative affect. The specific expression or manifestation of this negative affective bias may be influenced by cognitive manipulations (Lazarus, 1967), but we believe that the range of outcomes would still be limited to a negative affective domain. It is somewhat reassuring, especially considering their possible adaptive significance, that our true emotions may be more rationally determined and less susceptible to transient or whimsical situational determinants than has been suggested by Schachter and Singer. Perhaps we social psychologists should better appreciate our biological "hardware" or, to paraphrase a frequent media message, "It's not so easy to fool Mother Nature."

Postscript

[The] analyses sometimes suffer the imprint of someone convinced that he's right and willing to force his data to prove it. (Schachter, 1971, p. 141)

One function of replication studies is the independent assessment of the validity of conclusions drawn by investigators who sometimes force their data to fit their preexisting belief systems, thereby violating basic canons of scientific evidence. We began our research fully expecting to replicate Schachter and Singer's (1962) conclusion that inadequately explained, epinephrine-induced physiological arousal was readily manipulable into the disparate feeling states of euphoria and anger by varying available social cognitions. Our interest was to extend their analysis to the area of emotional pathology. After extensive testing, experimental variations, and procedural refinements designed to yield the predicted finding, we were forced to acknowledge the failure to replicate this now classic conclusion.

Obviously, there are many ways not to find an effect and few to demonstrate it. We now believe that both the basic paradigm and the methodology employed in the Schachter and Singer study and in our own may not be adequate to uncover the "emotional plasticity" predicted by their theory. But in addition, our data and that of Maslach lead us to propose the hypothesis that regardless of the experimental conditions utilized, awareness of one's strong arousal without adequate explanation is most likely to be interpreted as a negative mood state. Thus it may be that the extent to which states of unexplained physiological arousal are manipulable into disparate psychological mood states is limited to conditions of *mild* arousal (as Schachter and Singer's, 1979, current comments suggest, pp. 992–993. Some support for this constraint on the latitude of emotional plasticity comes from Nisbett and Schachter's (1966) inability to manipulate the emotion of subjects in a high-fear state, obtaining the misattribution effect only for subjects in a low-fear condition. Such clarification of the range or areas of applicability of a theory is another contribution of replication studies.

However, when Schachter and Singer's rejoinder now declares that *they* too "never found a difference," our failure to replicate becomes a replication of the null hypothesis and to some extent belittles our efforts. How could we—and, we presume, most other psychologists—have been led to misunderstand that the conclusions of the Schachter and Singer (1962) study were merely "tentative," based on nonsignificant treatment differences and internal analyses of questionable status? We were all led there by bold assertions to the contrary, by the rhetoric of conviction that Schachter and Singer chose to describe what they "really " found. "Conformation of Data to Theoretical Expectations" (p. 393) is their section heading, which belies any equivocation. It is important in this exchange to show briefly that both in their original article and in their present comments on our study and Maslach's, Schachter and Singer sometimes use their considerable literary talent to misdirect the reader's attention toward inadequately justified conclusions such that what was "never found" becomes one of the most cited findings in psychology textbooks.

Let us consider one instance of this misdirection. A one-sentence (cautiously worded) disclaimer of their findings can indeed be found: "However, the fact that we were forced, to some extent, to rely on internal analyses in order to partial out the effects of experimental artifacts inevitably makes our conclusions somewhat tentative" (Schachter & Singer, 1962, p. 396). This lean statement is sandwiched between an opening sentence that proclaims, "The pattern of data, then, falls neatly in line with theoretical expectations," and the following forceful conclusion:

> It has been suggested, first, that given a state of physiological arousal for which an individual has no explanation, he will label this state in terms of the cognitions available to him. This implies, of course, that by manipulating the cognitions of an individual in such a state we can manipulate his feelings in diverse directions. Experimental results support this proposition for following the injection of epinephrine, those subjects who had no explanation for the bodily state thus produced, gave behavioral and self-report indications that they had been readily manipulable into the disparate feeling states of euphoria and anger.
>
> From this first proposition, it must follow that given a state of physiological arousal for which the individual has a completely satisfactory explanation, he will not label this state in terms of the alternative cognitions available. Experimental evidence strongly supports this expectation. (pp. 395–396; reiterated verbatim in Schachter, 1971, p. 23)

We would like to propose that these conclusions should be recoded by psychologists as follows: There is *no* evidential basis for the empirical conclusion that epinephrine-aroused subjects can be readily induced to experience (or label that arousal as) euphoria or anger by manipulating available social cognitions (through a confederate's behavior).

Schachter and Singer's (1979) rejoinder cites the results of a study by Erdmann and Janke (1978) whose "results are consistent with ours and present none of the interpretative problems of the Marshall and Zimbardo and Maslach studies" (p. 992). However, they did not state what those "interpretative problems" are, nor did they mention several critical points about the Erdmann and Janke study. Unlike epinephrine, the drug used in the study (ephedrine) has strong central effects; the study failed to find any expected physiological differences, and the final conclusion advanced by the authors was the following:

> Regarding Schachter's theory the results and the conclusions of the present experiment imply that the relationship between emotional and physiological arousal might be less tight and/or less general than the theory proposes. (Erdmann & Janke, 1978, p. 73)

Dosage Levels, Source Awareness, and Plasticity

Since we found no differences between placebo controls and epinephrine-injected subjects, the drug dosage was increased (by tailoring level to body weight, a standard procedure in drug studies) to generate sufficient arousal differences for demonstrating possible emotionality effects of the manipulated social cognitions. Schachter (1971) led us to believe that emotionality was a direct, not a curvilinear, function of arousal by his reference to "the proposition that the degree of emotionality is directly related to the degree of physiological arousal" (p. 35). In their rejoinder, Schachter and Singer (1979) say that it is so obvious that the function is U-shaped as to be unworthy of mention. What may be worthy of mention are the parameters of that function, the specification of which should have been systematically investigated in humans. Having found weak effects on the subjects with their standard dose of epinephrine and the negative affect induced by our increased dosage (with inadequate explanation) does not justify their conclusion that our dose level put subjects on the other side of the curve. Clearly one cannot fit a U function with only two points. Moreover, it does not seem evident that the increase from .007 cc/kg (the equivalent of Schachter and Singer's .5 cc) to our .01 cc/kg would represent a vast difference on an inverted-U curve leading to performance reversal. We know of no empirical literature to support such an inference. The magnitude of the physiological reactions and self-reports of our increased arousal subjects were not qualitatively different from standard arousal subjects. (As can be seen in the data in our Table 1, the mean palpitation index was .9 for the standard dose subjects and only slightly higher, 1.4, for the increased arousal group.) In the animal literature cited by Schachter (1971), no differences were found for a 2:1 dosage ratio (p. 38), and to get dramatic debilitating effects the dosage ratio was pushed to 20:1.

Switching from rats to Schachter and Singer's (1979) phenomenological reports of their drug reactions, not one of our subjects ever reacted with anything resembling their near-to-death sensitivity. Of course, we and our graduate assistants pretested all drug doses on ourselves before administering them to any subject. The effects were remarkably variable. Marshall was hardly bothered by the .01-cc/kg dose, Zimbardo's experience was more marked, and the reactions of four others were arrayed from mild to strong.

When one's immediate physical reaction to a drug is intense, then the direct consequence is the perception that something is "very wrong" and the feeling is "lousy." In short, such a condition is not amenable to manipulation into positive moods by social cognitions—according to the current comments by Schachter and Singer (1979, p. 991). They state further that adrenaline alone produces a negative state when animals are in disturbing situations (pp. 991–992). Following their lines of argument, we would restate our position as follows: In unfamiliar settings (like those faced by the subjects in these experiments), the awareness of strong physical arousal symptoms in the absence of an adequate explanation creates a disturbing situation that is likely to be appraised in negative affect terms. Strong unexplained arousal states, then, should exhibit a negative bias, which is likely to be resistant to the blandishments of external social cognitions that are positive. That is a central conclusion of our research.

All of the evidence advanced by Schachter and Singer (1979) regarding the drug studies done in the 1920s and '30s (p. 994) is irrelevant both to our point and the necessary conditions for testing their two-factor theory of emotion. Subjects must find themselves aroused without adequate explanation in order for there to be a "bodily state in search of an appropriate cognition." In the studies by Marañon, Cantril and Hunt, and Landis and Hunt, cited by Schachter and Singer (1979), the subjects were fully aware of their arousal; they had a totally adequate explanation of its source in the injection they received. The "cold" or "as if" emotions shown by the majority of these subjects are not pertinent to our analysis, because we are interested in understanding the psychological experience of affect when particular somatic elements are present as part of an emotion, and not simply in a person's description of his or her somatic state.

It must be noted that *repeated* exposure to drug-induced arousal with a known physical source was typical for many of the Cantril and Hunt subjects. Such a condition is qualitatively different from those we are concerned with and have studied in the analysis of the consequences of unexplained arousal. Moreover, the "genuine-emotion subject" selected by Schachter and Singer (1979, p. 994) to illustrate that reactions to adrenaline can be pleasant, also reported "cold emotions" at another episode and also reported strongly negative consequences of arousal: "Extreme fear was present, but no con-

tent for it at the time. . . . I was intensely afraid" (p. 305).

Unfortunately, the bias of researchers willing to force the evidence to prove their point also is evident if one reads the original Landis and Hunt paper and Schachter and Singer's (1979) summary of it. Hysterical laughter does not tell us anything about the internal subjective state experienced by the institutionalized "lunatics" used as subjects. Landis and Hunt (1932) make quite explicit the difference between "outward and manifest expressive emotional reactions." Despite the overt hysteria, all cases labeled "emotion-subjective" were *negative*. This is exactly what Schachter and Singer would have predicted if they were using these data to support their earlier point about the negative effects of large doses of adrenaline. The Landis and Hunt subjects received much larger doses than our increased arousal subjects. Their reactions were quite variable but intense. One subject (classified "dementia praecox") reported feeling "pretty nervous" at 1.0 cc and laughed hysterically at 1.5 cc, while another in a manic phase had a crying spell at 1.0 cc and hysterical laughter at 1.5 cc.

This evidence again underscores the need for Schachter and Singer and all who work in the area of emotion to acknowledge the difference between public expressions of emotional reactions and the subjective experience of emotion. The two are rarely correlated in any of the studies on "emotional plasticity" or misattribution. The overt behavior may not reflect underlying affect at all, but rather conformity to situational contingencies. In our research and that of Maslach, many subjects faced with the antics of a euphoric confederate gave positive overt reactions, even laughed, but that behavior was independent of their self-reported affect, which was usually negative.

This same inconsistency shows up in Schachter and Singer's (1962) original data (the internal analyses used to salvage the study do not even present self-reported affect data) and is more glaring in Schachter and Wheeler (1962). The significant finding that is emphasized is that placebo subjects gave less overt laughter to a slapstick movie than did epinephrine subjects. However, on an overall amusement index, placebo subjects did *not* differ significantly from the epinephrine subjects (see their Table 3, p. 126), despite Schachter and Singer's (1979) fanciful relishing the contrary in their Footnote 3. Of greater import is the inability of Schachter and Wheeler to find any difference on self-reported reactions to the film. The means in their Table 4 are virtually identical for epinephrine, placebo, and chlorpromazine subjects: "funny," 4.1, 4.0, and 3.8, respectively; "enjoy it," 4.0, 3.9, and 3.8, respectively; "recommend it," 2.0, 1.9, and 1.8, respectively. All subjects reported that they felt the film was "mildly funny," they "enjoyed it a little," and would "recommend it moderately." This is hardly a pattern of data one would predict from Schachter and Singer's theoretical propositions.

Experimental Instructions

In response to an injection of epinephrine, "as far as the subject is concerned, the major subjective symptoms are palpitation, tremor, and sometimes a feeling of flushing and accelerated breathing" (Schachter & Singer, 1962, p. 382). Rothballer (1959), an expert on the effects of the drug, finds that tremor is "almost invariably" noted; palpitation is "the next most common finding" (p. 510). Thus, to mislead subjects about their anticipated reactions, symptoms *other* than these primary ones were mentioned as the side effects of their injection by both Schachter and Singer and us.

In the original Schachter and Singer (1962) study, the symptoms suggested were headache, numbness, and itching. In our replication we also mentioned the irrelevant symptom of headaches, but changed numbness to coolness and itching to dryness of mouth. Our reason for doing so was intentionally to include some minor, occasionally reported symptoms associated with epinephrine in order to increase the validity of the general instructions. We felt that if subjects experienced some weak effects that were attributed to the drug, they would be more likely to believe in the validity of the physician's instructions. This should have given them *less* reason to suspect that their major reactions (tremor and palpitations) were drug-related, since the credible communicator did not include them in his description of anticipated side effects.

In Schachter and Singer's (1962) study, the epinephrine–misinformed subjects tended to report *fewer* of the false symptoms, headaches, numbness, itching, than some or all of the other groups. In rejecting the symptoms specified by the physician, these subjects may have also doubted her competence. In a thorough critique of this feature of Schachter and Singer's work, Kemper (1978) suggests that the epinephrine–misinformed subjects were likely to have perceived the whole study as "unscientific" because of the totally wrong symptom expectations they

were given. Our instructions, thus, were an attempt to make the misinformation treatment function more appropriately in operationally evaluating the two-factor model of emotion.

Schachter and Singer (1979) argue that in doing so we did not properly misinform our subjects, and that is the reason we failed to find even a "shred of support for [their] original findings." They remind us that Schachter and Wheeler (1962) found a significant "dryness of mouth" effect. Examination of those data reveal that on a 5-point scale, the mean reported degree of dryness for epinephrine subjects was a scant .7, while placebo subjects were different by only .4 units. We believe that the dominant symptoms experienced by our subjects were unaccounted for and that the conceptual essence of the misinformation procedure is satisfied.

We would argue further that there are more substantial procedural differences between our study and Schachter and Singer's that readers should note. They dropped epinephrine subjects who reported "virtually no" palpitations or changes in heart rate before making their between-conditions analysis. This questionable subject selection excludes those who may have been physically inactive (activity alone will accelerate heart functions). These are the very subjects likely to have been focusing on their internal arousal rather than hula hooping and thus responding more negatively to their unexplained arousal (as we found). Another key difference may be that their subjects did not know prior to their appearance that they were to be injected. Ours consented to being injected before finding themselves in a fait accompli situation.

There are other differences that might be dredged up to account for our failure to replicate Schachter and Singer's (1962) findings—but sight is lost of the fact that we replicated their null effects only too well, despite many surface differences in procedures. On the Schachter and Singer affect index, the mean of their placebo group is 1.6, while ours is 1.5. The comparison between the two epinephrine–misinformed groups shows their mean is 1.9; ours is 1.4. Although they never report standard deviations, these small differences (.5 scale units on a 9-point scale) are well within sampling error range. Thus, we found virtually the same degree of inconsequential treatment difference as they did originally.

"The most pressing and crucial need with regard to Schachter and Singer results is a replication," states Kemper (1978, p. 174), who goes on to comment that "the credence with which the findings have been greeted is somewhat surprising in light of the absence of confirmatory results from another experimenter *in which exactly the same findings were sought*" (italics in original).

We indeed sought to replicate what we thought were the important results found by Schachter and Singer and could not. We tried to salvage something of value from an unsatisfying failure to replicate this classic by adding treatments that extended and tested some boundaries of their theory of emotion.

All the available data from our study, Maslach's, and Schachter and Singer's should be open to the close scrutiny of readers who by now must be wary of possibly being misinformed by the personal biases of the researchers involved in this argument. We hope some important clarifications have emerged from this exchange and apologize for occasionally replying in kind to personal attacks on our good sense and sensibility. In the future we will heed Oscar Wilde's (1908) admonition: "Arguments are to be avoided; they are always vulgar and often convincing" (p. 52).

Comments on the Maslach and Marshall–Zimbardo Experiments

Stanley Schachter
Columbia University

Jerome E. Singer
Uniformed Services University of the Health Sciences, Bethesda, Maryland

This article addresses interpretive questions raised in the immediately preceding articles by Christina Maslach and by Gary D. Marshall and Philip G. Zimbardo.

First man: How's your wife?
Second man: Compared to what?
(H. Youngman)

The Maslach Study

On page 384 of our write-up (Schachter & Singer, 1962) of the epinephrine–emotion experiment we wrote, "Immediately [6] after the subject had been injected, the physician left the room and the experimenter returned with a stooge." Footnote 6 read:

> It was, of course, imperative that the sequence with the stooge begin before the subject felt his first symptoms for otherwise the subject would be virtually forced to interpret his feelings in terms of events preceding the stooge's entrance. Pretests had indicated that, for most subjects, epinephrine-caused symptoms began within 3–5 minutes after injection. A deliberate attempt was made then to bring in the stooge within 1 minute after the subject's injection.

The matter of timing is obviously crucial in all of these experiments. If the subject experiences palpitations, accelerated breathing, and so on *before* the emotion-inducing manipulation, there is obviously little possibility that he can "attribute" or "interpret" his physiological state in terms of the experimental manipulation and he must interpret it in terms of events preceding the manipulation (e.g., he is nervous about being in the experiment, excited about something that happened to him, getting sick, etc.).

In the crucial phase (Part 2) of Maslach's (1979) experiment, the sequence of events is as follows:

1. For roughly a 1-minute period the subject is exposed to a 15-word list on a memory drum.
2. There is a 1-minute recall test.
3. For the next minute, the subject is exposed to another 15-word list. The final word on this list is either the neutral word or the arousal word *start*.
4. There is a 1-minute recall test.
5. "Next, the subject and confederate were told to look through the materials in the folder and were then left alone" (p. 958). On the assumption that there was at least some brief description of what they were supposed to do with the "materials in the folder," this could have taken anywhere from a few seconds to a few minutes.
6. Only after they start looking through the folder does the confederate go into her act, and from the description, it seems that the first minute of this routine is essentially neutral, with little affective overtone.

Maslach's posthypnotic arousal suggestion was the following: "When you see the word *start*, your heart will beat faster, your breathing will increase, there will be a sinking feeling in your stomach, and your hands will get moist. You will feel all of these sensations as soon as you see the word *start*" (p. 958).

The word *start* appeared on the second word list, which was followed by a 1-minute recall test. Since Maslach uses performance on this recall test as proof that the posthypnotic suggestion has taken, it must follow that her subjects were in a state of arousal

In the public domain

for some minutes before the confederate even began his or her act.

In addition, we note that this is not the first time during this experimental session that subjects were thrown into this state of marked physiological arousal with no explanation possible from the preplotted script of the confederate. To check on the effectiveness of the hypnotic induction of arousal, the first part of the experiment consisted of a private session with the subject during which he or she was hypnotized, the arousal suggestion was planted, the subject was exposed to the cue word *start*, and his or her physiological responses were measured. In short, twice during the experimental hour, a subject experienced, suddenly and with no explanation (if we credit the effectiveness of the amnesic suggestion), palpitations, speeded-up breathing, a sinking feeling in his or her stomach, and sweaty hands. The first time this happened the subject had not yet met the confederate; the second time it happened, the subject was working on a memory drum task and the confederate had not yet said a word.

Because of these matters of timing, Maslach's experiment and results have little to do with our experiment or with our hypotheses. The study does, however, unequivocally prove that when for no apparent reason, a subject's heart starts pounding, his or her breathing accelerates, palms turn sweaty, and stomach sinks, his or her mood is not likely to be affected by the irrelevant behavior of a confederate that follows after the appearance of this bodily state. The study also proves that subjects who, again for no apparent reason, find themselves in this bodily condition are likely to describe themselves as in a lousier mood than do subjects to whom this does not happen.

Footnotes notwithstanding,[1] within her experimental context there is only one way for Maslach to prove her position, and that is to run a set of conditions in which the word *start* appears a minute or two *after* the confederate starts his or her happy or angry routine and where there has been no prior posthypnotic arousal. If she is right, she will find the same results in these conditions as in those already run. If we are right, she will find that subjects in the happy condition are happy.

The Marshall and Zimbardo Study: 1. Dosage Levels

As to the Marshall and Zimbardo (1979) study, we find ourselves both bemused and perplexed by their strategy of replication. The simple fact is that their experiment replicates ours all too well. We never found a difference between the conditions they chose to replicate, and neither do they. Having found what we did, they then ran an additional condition with markedly increased doses of epinephrine and found that this produced a state of negative affect. Then ignoring virtually everything else that we and others have done, they conclude on the basis of this, almost their sole positive finding, that "epinephrine-related physiological arousal does not provide 'emotional plasticity,' but rather shows a consistent association with negative affect" (p. 983). As Maslach (1979) summarizes these data, "When the arousal was made stronger and more salient, subjects reported a *negative* emotional state, rather than the positive 'euphoria' predicted by Schachter and Singer" (p. 954).

In fact, Schachter and Singer would have predicted nothing of the sort. Maslach, Mar-

---

[1] Apparently in response to comments made by us in previous communications, Maslach discusses these issues in her Footnotes 7 and 10. Footnote 7 rejects the prior-arousal possibility by citing, without data, a pretest that could contain the faulty-timing artifact, and by citing an unpublished manuscript (Zimbardo & Maslach, Note 1). Footnote 10 raises three arguments against the faulty-timing objection. The first raises a new distinction—between normative and causal information—and claims that for causal information the confederate's actions must occur merely at the same time as the subject's arousal, not necessarily before the arousal. But that misses our point: The confederate need not start before the arousal but will certainly be of little effect if he or she starts after the arousal has occurred and a label has already been chosen. The reason for starting early is to assure that the unexplained arousal does not occur in the absence of a reasonable social context. Arguments 2 and 3 presuppose uncritical acceptance of the Marshall and Zimbardo article, while Marshall and Zimbardo presuppose uncritical acceptance of the Maslach article.

shall, and Zimbardo do not mention the fact, but we have been explicitly concerned with the effects of dose on emotional behavior, and in Schachter (1971), we reported experiments and reviewed evidence that small doses of epinephrine facilitate emotionally mediated behaviors in animals, whereas large doses interfere with such behavior. As dose increases, animals move less, get sick, and at large enough doses, die. Obviously we have done no counterpart to these dose experiments with humans, but it hardly seemed necessary, for in searching for a feasible dosage of epinephrine in our original experiment, we ourselves tried doses as heavy as, and heavier than, that used by Marshall and Zimbardo in their increased arousal condition. We would not do it again and can only assume that Marshall and Zimbardo never tried their increased dose on themselves or, if they did, that they are made of considerably stronger stuff than are we. At this dose, we did not have palpitations—our hearts pounded; we did not have tremors—we shook. We might have been convinced by someone that we were about to die, but no amount of social psychological tomfoolery could have convinced us that we were euphoric, or angry, or excited, or indeed anything but that something was very wrong and that we felt lousy. The point has always seemed too obvious to dignify with the status of the formal hypothesis that for humans, too, there is an inverted-U relationship between adrenaline dosage and the effectiveness of an emotion-inducing manipulation.

Other Research Evidence

We concede that we read Marshall and Zimbardo's (1979) description of our results with wistful envy. When they report that they were intrigued "to discover the reported ease with which the same condition of physiological arousal could be steered in as seemingly opposite affective directions as happiness or anger as a result of these cognitive manipulations" (p. 971), they certainly are not describing our experiment. The elaborate stage setting, the large cast, and the attention to exquisite nuances of dosage and timing yielded results requiring two internal analyses and three supplementary studies to make our point. Our conclusions about emotion were hardly based on this experiment alone, and we believe that there was no write-up of this study in which we did not make explicit what we believed was wrong with the experiment and did not point out the gross inadequacies of the data and then go on to describe the further research that did support our propositions. It was not that we were particularly humble about our work; we simply did not want to seem to be nitwits by basing a theoretical structure on obviously inadequate data.[2]

Since Maslach, Marshall, and Zimbardo either disregard or, to our mind, misinterpret this supporting material, we shall review this literature. First, Schachter and Wheeler (1962) examined subjects' reactions to a slapstick movie. In terms of quiet reactions, such as smiling, there were no differences between subjects injected with adrenaline and those injected with placebo. In terms of broad reactions such as laughter, epinephrine subjects laughed significantly more than did placebo subjects. As far as raucous reactions are concerned, 16% of the epinephrine subjects belly laughed; not a single placebo subject did so ($p < .01$)—hardly the pattern of findings one anticipates from an agent that produces a bias toward "negatively toned reports of affect."[3]

On negative emotions such as fear, we did a number of animal studies, of which the most relevant was Singer's (1963) demonstration that in neutral situations, an animal injected with adrenaline is no more disturbed or fearful than a control animal. In frightening situations, however, the adrenaline animal is mark-

---

[2] Relevant to the issue raised on pages 984–986 of the Marshall–Zimbardo Postscript, we suggest reading all of page 396 of our original article rather than the few sentences that Marshall and Zimbardo have selected from this page. Readers can then decide whether we have based our conclusions on this single experiment or whether we base them on the body of research that was generated by this study.

[3] Maslach also describes this experiment in her article. Anyone who relished Hastorf and Cantril's (1954) observations on the Princeton–Dartmouth game of 1951 should enjoy comparing these two descriptions to Table 3 and the pertinent paragraphs on pages 125–126 of the original article (Schachter & Wheeler, 1962).

Table 1
The Effects of Ephedrine and Placebo on Mood in Various Experimental Contexts[a]

Condition	Setting		
	Happiness	Neutral	Anger
Ephedrine	33.2	27.2	24.3
Placebo	28.5	30.7	30.8

Note. Higher scores indicate more pleasant ratings.
[a] From Erdmann and Janke (1978).

edly more frightened than a placebo animal. This is a result that in various forms has been replicated several times, most recently by Haroutunian and Riccio (1977). In and of itself, then, adrenaline does not produce a negative state in animals. Only in disturbing situations does it do so.

As to replications and related studies conducted since our group was working on these studies in the early 1960s, we simply have not followed the literature systematically, and in preparing these comments we have not had sufficient time to institute a thorough library search. However, what we have learned relevant to the issue of "emotional plasticity" seems to us to support our original findings. Though only we and Marshall and Zimbardo seem to have used epinephrine, on the whole, studies employing other sympathomimetic agents report findings consistent with our original findings. Erdmann and Janke (1978) relied on a well-disguised oral administration of the sympathomimetic agent ephedrine to manipulate arousal. They had an eight-condition experiment—four placebo conditions and four (in our terms) ephedrine–ignorant conditions (i.e., because of the mode of administration, subjects could have no idea of why they felt as they did). Crosscutting these conditions, Erdmann and Janke manipulated four emotional contexts: neutrality, happiness, anger, and anxiety. They measured the joint effects of context and arousal on self-reports of mood using both rating scales and a standardized adjective checklist. For the conditions relevant to this article, their results were as shown in Table 1 for the mood scale derived from the adjective checklist.

The three placebo conditions do not differ. With ephedrine, however, the conditions diverge, and in the predicted directions. The ephedrine–happiness group is more euphoric than the ephedrine–neutral group, which in turn is happier than the ephedrine–anger group. These results are consistent with ours and present none of the interpretive problems of the Marshall and Zimbardo and Maslach studies. Given the Maslach–Marshall–Zimbardo hypothesis that sympathomimetic agents bias people toward negative affect, it is of interest to note that only in the anxiety conditions did ephedrine fail to have an effect—a finding that Erdmann and Janke attribute to the ceiling effect.

We note, too, that our interactionist view of emotion has become something of a model for studies of a variety of psychopharmacological agents. For at least two agents, marijuana and alcohol, there have been studies that clearly demonstrate that whether or not these agents produce positive, negative, or neutral affective states depends on the interaction of the physiological effects of these agents with cognitive, social, and situational factors (Pliner & Cappell, 1974; Rossi, Kuehnle, & Mendelson, 1978). Obviously, all of the work on the effects of set on the action of drug agents makes much the same point (Wikler, 1957).

The Marshall–Zimbardo Study: 2. Experimental Instructions

Given this background material, it hardly seems an exotic hypothesis to repeat our suggestion of almost 20 years ago that adrenaline, too, in mild doses, produces a state of autonomic arousal that of itself is neither pleasant nor unpleasant but to a considerable extent takes on its affective coloration from the situation. How then can we account for Marshall and Zimbardo's results in their basic epinephrine and placebo conditions? In these conditions, unlike the increased arousal condition, their dose was the same as ours, yet consistently on self-report and activity measures their epinephrine subjects were somewhat unhappier than placebo subjects. Although, given the inadequacies of our experimental design, we do not expect significant differences between these conditions, at the very least

our line of thought would lead us to expect that, as in our experiment, the epinephrine–basic subjects would be slightly more, not less, euphoric than placebo–basic subjects.

Since the two experiments differ in numerous, possibly consequential, ways, it is obviously guesswork to try to understand why Marshall and Zimbardo fail to find even this shred of support for our original findings, but we have a pretty good guess. Marshall and Zimbardo attempted to replicate what we called the epinephrine–misinformed condition. The original instructions in this condition were:

> I should tell you that some of our subjects have experienced side effects from the Suproxin. These side effects are transitory, that is, they will only last for about 15 or 20 minutes. What will probably happen is that your feet will feel numb, you will have an itching sensation over parts of your body, and you may get a slight headache. (Schachter & Singer, 1962, p. 383)

None [4] of these symptoms, of course, are consequences of an injection, and in our study these instructions were deliberately designed to provide the subject with an inappropriate explanation of his bodily feelings.

For no reason we can fathom,[5] Marshall and Zimbardo decided to change our symptoms, and their instructions were the following:

> I should mention that although there are usually no side effects to the injection, a few of our subjects have reported some minor transitory reactions that may have resulted from the injection. These have typically included a feeling of dryness in the back of the mouth or throat, or a feeling of coolness in the hands or feet, and a couple of people have reported a slight headache. (Marshall, 1976, p. 13)

Unfortunately, both dryness of mouth and coolness in the hands or feet are consequences of an injection of adrenaline, and rather than having the counterpart of our epinephrine–misinformed condition, Marshall and Zimbardo to some extent have the counterpart of our epinephrine–informed condition. In the Schachter and Wheeler (1962) study, one of the questions asked to assess the effects of the drug manipulations was, "Does your mouth feel dry?" In Table 1 of that article it can be seen that subjects injected with epinephrine reported significantly ($p < .01$) more dryness than subjects injected with placebo. On the question of coolness of limbs, it is well known that adrenaline causes marked peripheral vasoconstriction, and several studies (e.g., Bierman, 1941; Wenger et al., 1960) have demonstrated that epinephrine causes a marked decrease (as much as 5 °C) in the temperature of the limbs. An injection of epinephrine will produce both a feeling of dryness in the mouth and a feeling of coolness in the hands and feet.

The Marshall and Zimbardo basic epinephrine condition can hardly, then, be considered the counterpart of our epinephrine–misinformed condition. If anything, it is somewhat comparable to our epinephrine–informed condition, in which the subjects were given an accurate description of their symptoms. This condition was designed to test the hypothesis that when subjects have an appropriate explanation for their physiological symptoms, they will be unlikely to label their feelings in terms of the alternative cognitions available. This proved to be the case, since subjects in the euphoria–epinephrine–informed condition of our experiment were less happy than placebo subjects. We suggest that this finding is inadvertently replicated in the Marshall–Zimbardo experiment.

Obviously, we are unconvinced that either the Maslach or the Marshall–Zimbardo experiments demonstrate what is claimed for them. We believe that the various experimental problems we have identified invalidate the conclusions drawn from these studies. Oddly enough, however, the simplest and most direct test of the major conclusion drawn by these

---

[4] The pharmacological texts (Goodman & Gilman, 1975) list "headache" as one of the effects of an injection of epinephrine. At the doses we used, this proved not to be the case, as can be seen in Table 1 of the Schachter and Singer (1962) article. In our pretests, however, headaches did sometimes accompany heavier doses of adrenaline.

[5] Relevant to Marshall and Zimbardo's postscript justification for these changes in procedure, we note that we have read Marshall's PhD dissertation carefully and nowhere in the 224 pages of text that is heavily concerned with differences between his study and ours is there any justification for changing the symptom description from "numbness to coolness and itching to dryness of mouth" (Marshall & Zimbardo, 1979, p. 987). In fact, nowhere in the entire text is this change even mentioned. These are simply referred to again and again as "irrelevant symptoms."

authors would bear little resemblance to either their experiments or ours.

Evidence on Emotional Plasticity

Clearly, Marshall, Maslach, and Zimbardo feel that their experiments are more than just a failure to replicate; they signal a fundamental deficiency in our model. Emotions, they claim, are not really so plastic. While there is no fundamental disagreement between us concerning the need for both arousal and an appropriate cognition, they suggest that the ultimate label of the physiological state associated with adrenaline is always likely to be unpleasant. Marshall and Zimbardo (1979) summarize their own and Maslach's work in these words, "The general picture that emerges . . . indicates that epinephrine-related physiological arousal does not provide 'emotional plasticity,' but rather shows a consistent association with negative affect" (p. 983).[6]

The test of the hypothesis that such arousal is unpleasant requires neither our cumbersome set of studies nor the equally complicated Marshall, Maslach, and Zimbardo replications. All it requires it that a number of people be injected with adrenaline and asked to describe how they feel—precisely the studies done in the 1920s and '30s by Marañon (1924), Cantril and Hunt (1932), and Landis and Hunt (1932). These studies are cited by Marshall and Zimbardo, but our reading of them differs considerably from theirs. They restrict themselves only to Marañon's subjects, who report "true" emotions and neglect the larger group who reported "cold" or "as if" ones. But the point at issue is not whether exogenous adrenaline produces an emotion rated in Marañon's context as genuine, but whether it produces a feeling of unpleasantness. The "cold" emotions, as far as we can determine from Marshall, Maslach, and Zimbardo's theory, are as pertinent to this point as any. This is especially true since Marañon suggests that "real" emotions following the injection are most likely to occur in those people with a prior endocrine disturbance or a history of affective disorder.

Marañon (1924) does not systematically categorize the reactions of his subjects, but from the various quotations throughout his article, it is evident that his subjects ran the full gamut of reactions from the negative "I feel as if I were afraid" to the exultant "something which comes up from the guts as when one is awaiting a great happiness" (p. 309). Cantril and Hunt (1932) find no evidence of a uniformly negative affective reaction to adrenaline. In their Table 1, entitled "Summary of the Results of the Experiment," one out of the four cases of genuine emotion was a pleasant one, and in 11 cases of reported affect, 3 were pleasant, 3 were unpleasant, and 5 were indifferent. The following self-description, from a genuine-emotion subject, certainly does not appear to us as the product of a bias toward negativism:

> Excitement (have felt like this in large class when I think I have a good idea, when raising my hand). No elation, but a background of elation. Feel light, as I used to in a burst of creative activity (writing). A pleasant state, possibly by association with such activity. Not unfamiliar. Used to attempt to bring on such states deliberately in adolescence. . . . During times of tremendous intellectual experiences in the past, times when my vision seemed peculiarly clear and far reaching, I have experienced similar reactions, but not even then so strongly. A tremendous illusion of power, vitality. (p. 303)

Landis and Hunt (1932) report results that may be unrepresentative, since they used institutionalized lunatics as subjects, but here, too, the authors report considerable variety in emotional response. Following the injection, three of their subjects had weeping fits, and three of their subjects broke into giggles or

[6] It is difficult to determine if Marshall and Zimbardo feel that the state of arousal induced by epinephrine is of itself sufficient to produce negative affect or if it requires an inadequate explanation as well. The quotation above suggests that the arousal state alone is sufficient; in other places they seem to indicate that an "inadequate explanation" is also required. In either case, their experiment has nothing to do with the question, for they do not manipulate the adequacy of the explanation. Our own results suggest that contrary to what we believe are Marshall and Zimbardo's expectations, providing a subject with an adequate explanation of his or her arousal state will, in euphoria conditions, worsen his or her mood. Our epinephrine-informed subjects were deliberately told what they would feel and why. Such subjects reported themselves as significantly *less* euphoric than subjects who had no adequate explanation for their bodily state.

hysterical laughter—hardly the uniformly negative affective tone required by the Marshall, Maslach, and Zimbardo formulation. Landis and Hunt conclude, "The adrenaline syndrome may be the basis for either pleasant or unpleasant emotional experiences" (p. 484).

To add our own bit, the sensation was for us curious and exhilarating—a feeling of emotional déjà vu. We had felt this way often in the past, but in this laboratory context it made no sense to feel this way—a pure arousal state uncluttered by passion or fear, affection or hatred. It was neither pleasant nor unpleasant; it was, though, absorbing enough so that at mild doses, we were delighted to serve as our own subjects again and again.

In these days of ethical guidelines and human subjects committees, this may very well be the end of the matter, for it is unlikely that anyone will do experiments such as ours or Marshall and Zimbardo's for quite a while, if ever again. On the particular issue at stake, however, this is probably of little moment, for this is one issue on which the readers can serve as their own subjects. If they will do a thorough introspective job after convincing a physician to inject them with .5 cc of a 1:1000 solution of epinephrine, they can decide which of us is right—or would this, too, require the approval of a human subjects committee?

Bem Sex Role Inventory: A Theoretical and Methodological Critique

Elazar J. Pedhazur
New York University

Toby J. Tetenbaum
Fordham University

The rationale underlying the construction of the Bem Sex Role Inventory (BSRI), and the psychometric properties of the resulting instrument are scrutinized. Following a brief discussion of different types of sex role research, the results of two studies are presented and discussed. In Study 1, 1,464 graduate students rated the desirability of the BSRI traits for one of three referents: man, woman, or adult in American society. In Study 2, 571 graduate students used the BSRI for self-ratings. It was found that, regardless of the referents used, the "masculine" traits were relatively high in desirability but some of the "feminine" traits were low in desirability. Discriminant function analyses revealed that discrimination among groups was primarily due to the differential ratings of the two traits Masculine and Feminine for the different referents. Results from factor analyses of the ratings of desirability and the self-ratings indicated that (a) Bem's classification of the BSRI traits into masculine, feminine, and neutral is not tenable; (b) the dimensions that underlie desirability ratings differ from those that underlie self-ratings; and (c) the dimensions of self-ratings of males differ from those of females. The article concludes with a discussion of the implications of the findings for the measurement of androgyny.

Although sex roles have been a subject of study for some time, interest in them has greatly intensified as a direct result of the activities and writings dealing with, or emanating from, the women's liberation movement. (For a review of sex role research, see Hochschild, 1973, and, more recently, Ruble, Frieze, & Parsons, 1976.) Investigations of masculinity, femininity, and androgyny have proliferated, emphasizing such aspects as historical perspective (Bullough, 1973; Hunter, 1976; Taylor, 1973), development (Block, 1973; Block, Van der Lippe, & Block, 1973; Maccoby & Jacklin, 1974; Rebecca, Hefner, & Oleshansky, 1976), psychological and sociological correlates (Maccoby & Jacklin, 1974; Parsons, Ruble, Hodges, & Small, 1976), and paradigms for change (Bernard, 1975, 1976; Lipman-Blumen, 1973). Definitions of masculinity (e.g., Brannon, 1976; Pleck, 1975, 1976), femininity (e.g., Sherman, 1971, 1976; Steinmann & Fox, 1966), and androgyny (e.g., Bem, 1974, 1975) similarly abound.

There is a wide variety of instruments purportedly designed to measure masculinity and femininity—for example, the *Fe* scale of the California Psychological Inventory (Gough, 1957); the *Mf* scale of the Minnesota Multiphasic Personality Inventory (Hathaway & McKinley, 1943); the GAMIN M scale (Guilford & Zimmerman, 1949); and the Stereotype Questionnaire (Rosenkrantz, Vogel, Bee, Broverman, & Broverman, 1968). In an extensive review of such instruments, Constanti-

This research was supported by a Fordham University Faculty Research Grant. The computation for this study was supported by the Courant Institute of Mathematical Sciences at New York University, which is supported by the Department of Energy under Contract EY-76-C-02-3077.

We wish to thank Sheldon Kastner and Marvin Sontag for commenting on an earlier version of this article and for discussing various aspects of the study. Appreciation is extended to Gunārs V. Lucāns and Bert Holland for their assistance in computer programming.

nople (1973) concluded that they were inadequate on theoretical as well as psychometric grounds. In addition to questioning definitions of masculinity and femininity as operationalized by existing measures, Constantinople's primary criticism was directed at the assumptions of unidimensionality and bipolarity that seem to underlie the construction and use of masculinity–femininity measures. She concluded that the available evidence indicates that masculinity and femininity are neither bipolar nor unidimensional.

Reflecting similar concerns about the treatment of masculinity and femininity as antithetical, Bem (1974) constructed the Bem Sex Role Inventory (BSRI) to measure the two attributes as orthogonal dimensions, and also to yield an androgyny score. In the present article the rationale underlying the construction of the BSRI and its psychometric properties are scrutinized. It should be noted that much of what is said about the BSRI applies also to various other sex role measures currently in use. The BSRI was chosen because of its great popularity, and because, from a perusal of research studies in which it was used and from statements about it in recent textbooks (e.g., Oskamp, 1977; Wrightsman, 1977), it appears that its validity has been accepted without much critical questioning.

Hochschild (1973) has identified four broad types of research in sex roles. One type, for example, deals with sex roles as reflected in actual or attributed sex differences in personality traits, interests, and the like. Another type focuses on appropriate behaviors for males and females. Regardless of the relative merits of the different types of sex role research, failure on the part of a researcher to use an unambiguous definition of the type of sex roles being investigated is bound to result in the construction or use of measures of dubious validity, as well as in ambiguities in the conceptualization and execution of the research. Moreover, explicit delineations and specifications are necessary within each type of sex role research. For example, is one investigating role expectations or role enactments (Sarbin & Allen, 1968)? Are sex differences in traits studied normatively or prescriptively? (For a detailed discussion, see Spence, Note 1.)

Bem's work was done in the context of trait stereotyping. Consequently, it is important to bear in mind the potential problems and ambiguities associated with research in stereotyping. For example, some researchers use the "everyday" or "commonsense" conception of stereotypes, which is usually considered to be narrow and pejorative. Other researchers are primarily interested in one or more of the following aspects of stereotypes: their complexity, function, accuracy, resistance to change, to name but a few (Fishman, 1956; Vinacke, 1957). Bem offers no clear statement about the aspect, or aspects, of stereotypes in which she is interested, except to say that her concern is with positive traits only.

Also, it has been demonstrated that the format and the conditions under which stereotypes are elicited affect the results. For example, Erlich and Rinehart (1965) provided respondents with either a trait checklist or an open-ended format for the purpose of describing different ethnic groups. It was found that respondents given the checklist used a larger number of traits and exhibited greater consensus than did those who responded to the open-ended format. A probably more important finding was that the trait list obtained with the open-ended format was considerably different from the one used in the checklist format. Dealing specifically with stereotyping of a woman, Clifton, McGrath, and Wick (1976) have demonstrated that different traits were attributed depending on the role ascribed to her, for example, housewife, bunny, athlete.

With the above comments in mind, we shall proceed to examine the method used in the construction of the BSRI. Basically, judges were asked to rate the desirability of approximately 400 personality traits either for a man or for a woman in American society. Tests of significance of the difference between the mean ratings of each item were performed. Twenty traits rated significantly more desirable for a man than for a woman were designated as masculine, and 20 traits rated significantly more desirable for a woman than for a man were designated as feminine. In addition, 20 traits whose mean ratings of d

sirability for a man and for a woman did not differ significantly were designated as neutral. Having thus selected the traits, Bem proposed that the BSRI be used as a self-rating instrument, in which the respondent is asked to indicate on a 7-point scale, ranging from "never or almost never true" to "always or almost always true," the degree to which each trait describes himself or herself. "Masculinity equals the mean self-rating for all endorsed [sic] masculine items and Femininity equals the mean self-rating for all endorsed [sic] femininity items" (Bem, 1974, p. 158). Two additional scores can be obtained from the responses to the BSRI: an Androgyny score, which is essentially the discrepancy between the Masculinity and the Femininity scores, and a Social Desirability score, which is the mean self-rating on the 20 "neutral" traits. (For further details, see Bem, 1974.)

Of the various problems and issues related to the construction and use of the BSRI, only several will be noted at this stage. Instead of defining the domains of masculinity and femininity and attempting to construct measures consistent with the definitions, Bem has chosen a strictly empirical approach. While such an approach may have limited utility when the primary concern is with criterion-related validity, its appropriateness is very doubtful when the focus is on construct validity (e.g., Cronbach & Meehl, 1955; Travers, 1951). Regardless of one's viewpoint on this issue, however, it is important to examine some of the possible consequences and to indicate the basic requirements of the method of scale construction that Bem has used.

It is clear that Bem was studying the desirability of traits, or personality characteristics, for males and females. But since the meaning of the term *desirable* in the instructions was not clarified, it was open to different interpretations by respondents (e.g., normatively, prescriptively; see Strahan, 1975, and Spence, Note 1).

In the discussion of the rationale for the construction of the BSRI, the distinction between traits and behaviors is occasionally blurred, as is evidenced by the statement that "because the BSRI was founded on the conception of the sex-typed person as someone who has internalized society's sex-typed standards of desirable *behavior* for men and women, these *personality characteristics* were selected as masculine or feminine on the basis of sex-typed desirability" (Bem, 1974, p. 155; italics added).

The fact that 400 *t* tests were treated as if they were independent of each other seems to require no elaboration. It is, however, important to note that when relying solely on tests of significance one runs the risk of overlooking the distinction between statistically significant and substantively meaningful findings.

The criterion employed for the designation of traits as masculine, feminine, or neutral seems to be based on the assumption that traits used to characterize one of the sexes are not, or should not be, used to characterize the other sex. No justification is offered for this assumption, which appears to be untenable on the basis of research on ethnic or racial stereotyping (see, for example, Erlich & Rinehart, 1965). One possible consequence of the trait selection procedure is that it may have resulted in the inclusion of traits that are not desirable but, rather, *less undesirable* for one of the sexes. In sum, the method of trait selection for the BSRI is not unlike the method occasionally encountered in other areas (e.g., achievement testing) where exclusive reliance on the statistical characteristics of the items (e.g., difficulty, discrimination) for their selection may lead a test constructor to neglect the most important property of the test: its validity.

It is necessary to identify the dimensions that underlie the relations among the ratings of trait desirability, and those that underlie the relations among ratings of traits when they are used for self-ratings. The demonstration that each of the proposed subscales is unidimensional is necessary for their valid use as summated rating scales, regardless of whether they were designed to be consistent with theoretical definitions of the constructs or whether they were arrived at empirically (Green, 1954). No evidence about the dimensions underlying the BSRI is provided by Bem.

To provide support for and amplify some

of the observations made above, two studies were undertaken: The first dealt with the ratings of desirability of the BSRI traits, and the second was concerned with the properties of the BSRI when it is used as a self-rating instrument. In an attempt to replicate Bem's work as closely as possible, her format and instructions were used despite some of the reservations expressed above.

Study 1: Desirability Ratings

The 60-item BSRI was administered to 1,464 graduate students of education attending one of three universities in New York City. The instructions were those used by Bem (1974) in the trait-selection phase of her study; that is, the subjects were asked to rate the desirability of each trait for a man or a woman in American society. In addition, the present study sought ratings of desirability for an adult in American society.

Descriptive Statistics

Means and standard deviations of desirability ratings are reported in Table 1. Also included in the table, for comparative purposes, are mean likableness ratings of traits common to the BSRI and to trait lists used in studies by Anderson (1968) and Bryson and Corey (1977).

Several points will be noted. The traits labeled by Bem as masculine are generally perceived as desirable when applied to a man. All the item means are greater than 5 on a 7-point scale, ranging from "not at all desirable" (1) to "extremely desirable" (7). The means for the same traits, while still on the desirable end of the continuum, are generally lower when the traits are applied to an adult, and lowest when they are applied to a woman. Note, however, that the standard deviations associated with the trait-desirability ratings for a woman are generally larger than those for a man or an adult, indicating less agreement among respondents when the traits are applied to a woman.

Overall, the mean ratings for traits designated as feminine tend to be lower than those designated as masculine, even when the former are applied to a woman. This is also noted when contrasting the mean ratings of the "masculine" and "feminine" traits for an adult. More important, however, is the finding that some of the "feminine" items are perceived as relatively undesirable, or negative. See, for example, the means for the traits Shy, Gullible, and Childlike. Not only are these traits rated low in desirability when they are applied to a man or an adult, but their desirability is also low even when the referent is a woman. These findings cast doubt about Bem's (1974, 1975, 1977) statements that the "masculine" and "feminine" traits are positive, or socially desirable. In fact, Bem indicates that she included 20 "neutral" traits, 10 positive and 10 negative ones, as a means of checking whether the responses to the "masculine" and "feminine" traits are affected by a social desirability response set. The negativity of some of the "feminine" traits is underscored when their mean ratings are compared with the mean ratings of "neutral" traits designated by Bem as being negative. For example, the mean ratings of the "feminine" traits Gullible and Childlike are lower than the mean ratings of the "neutral" traits Theatrical, Unpredictable, Jealous, and Secretive.

About half of the traits on the Masculinity and Femininity subscales of the BSRI appear also on the list of traits rated for likableness in a study by Anderson (1968), who says: "Sex-linked words were . . . deliberately omitted from the list" (p. 277). The overlap between the two lists is actually greater when one considers not only identical words but also close synonyms. Rosnow, Wainer, and Arms (1969) indicate that certain of the traits used by Anderson are sex linked, and others are not. Among the latter are Loyal and Shy, which Bem designated as feminine traits, and Ambitious, which according to Bem is a masculine trait. The situation becomes more complicated as one considers additional studies of trait ratings. For example, Bryson and Corey (1977) asked subjects to indicate, in addition to ratings of likability, the sex-relatedness of a set of traits. They found that for some traits designated as masculine or feminine there were neither sub-

Table 1 (*continued*)

Trait	Man[a]	Woman[b]	Adult[c]	Anderson (1968)	Bryson and Corey (1977) Male	Female	General
57. Adaptable	5.21 (1.21)	5.16 (1.21)	5.58 (1.18)	—			
58. Unsystematic	1.85 (1.17)	2.30 (1.38)	1.79 (1.16)	—			
59. Tactful	4.87 (1.19)	5.50 (1.16)	5.23 (1.21)	4.94			
60. Conventional	3.94 (1.50)	4.34 (1.60)	4.13 (1.56)	2.60			

Note. N = 1,464. BSRI = Bem Sex Role Inventory. Standard deviations appear in parentheses. To facilitate reading and interpretation, traits have been grouped by scale rather than as they appear on the BSRI. Thus, Traits 1–20 are considered by Bem to be masculine; Traits 21–40, feminine; and Traits 41–60, social desirability. Traits on the BSRI and Anderson were rated on a 7-point scale, whereas traits on Bryson and Corey were rated on a 10-point scale. Since the BSRI scale ranges from 1 to 7, whereas the Anderson scale ranges from 0 to 6, for purposes of comparability a constant of 1 was added to each mean on the Anderson data.

[a] n = 493.
[b] n = 426.
[c] n = 545.

stantively meaningful nor statistically significant differences between the mean ratings of their likability for males and for females. Examples of such traits are Conceited, which was classified as masculine, and Gullible, which was classified as feminine. Using Bem's criterion for trait selection, both traits would have to be classified as neutral. Parker (1969) provides a list of feminine traits, which includes the following: Helpful, Moody, Conscientious, Sincere, Friendly, and Conventional. These are among the traits classified as neutral by Bem. Applying Bem's criterion for the designation of traits as sex related to the results of the present study, one would have to conclude that 16 of the traits classified as neutral on the BSRI are actually sex related because the differences in the mean ratings of their desirability for a man and for a woman are statistically significant. If one were to add a criterion of meaningfulness, some of the traits would still have to be classified as sex linked. For example, using both criteria, the traits Helpful, Theatrical, Unpredictable, Sincere, Happy, Friendly, Tactful would have to be classified as feminine, whereas on the BSRI they are treated as neutral.

The examples above highlight some of the difficulties that may be encountered when trait selection is based solely on the criterion of statistical tests of significance. The power of the statistical test depends, among other things, on the size of the groups used. Consequently, given sufficiently large groups, any difference between their means may reach a prespecified level of statistical significance. The contradictory findings reported above may also serve to underscore the dangers in drawing conclusions on the basis of results obtained from "samples" of convenience. While this state of affairs is not unique to research in sex roles, it is unfortunate that some researchers in this area present their findings as "norms," and that other researchers proceed and interpret their own findings in relation to such "norms."

Discriminant function analysis. It will be recalled that Bem has performed about 400 univariate tests of significance in the trait-selection phase of her study. In the present study, the ratings of the desirability of the 60 BSRI traits for an adult, for a man, and for a woman were subjected to a stepwise discriminant function analysis. In addition, a separate analysis was done of the ratings for a man and for a woman, in order to determine the type of results Bem might have obtained

Table 2
Discriminant Analysis of Trait Desirability for a Man, for an Adult, and for a Woman

Group	Traits	Function	R_c^2	Λ	χ^2	*df*	% of trace	% correct classification	Centroids 1	Centroids 2
Man									2.34	.63
		1	.817	.183	2434.47	61	89.35			
Adult	60							88.9	.22	−.94
		2	.348	.652	612.13	59	10.65			
Woman									−2.99	.48
Man									2.27	−.37
	Masculine	1	.803	.197	2372.66	3	95.40			
Adult								87.0	.16	.57
	Feminine	2	.164	.836	261.23	1	4.60			
Woman									−2.83	−.30
Man									2.66

		1	.883	.117	1965.35	2	100.00	97.7		
Woman	Feminine								2.95	

Note. R_c^2 = squared canonical correlation. All the chi-squares are significant beyond the .001 level. *n*s = 493 (man), 545 (adult), and 426 (woman).

had she performed a multivariate analysis.[1] Despite our expectation that the major contribution to the separation among the groups would be made by the two traits Masculine and Feminine, no hierarchy for the inclusion of traits in the analyses was preestablished. The results of the analyses are summarized in Table 2.

It will be noted that while both functions are statistically significant, the first one accounts for the bulk of the differences among the three groups, namely 89% of the trace. From the centroids associated with the first function, it is evident the three groups are separated about evenly on this dimension, with the adult group being in the middle. The second function, on the other hand, reflects primarily differences between trait desirability for a man and for a woman, as contrasted with the adult group.

Among indices used to study the relative contribution of each of a set of variables to a discriminant function are the standardized coefficients and the structure coefficients, the latter being the correlations of each variable with the discriminant function (see, for example, Cooley & Lohnes, 1971). Although we prefer the use of structure coefficients, both types of indices will be discussed. Because of space limitations the entire functions and the structure coefficients associated with them will not be reported. Instead, it will be noted that while the standardized coefficients associ-

[1] Each of the groups was composed of male and female respondents. Except for a very small number for whom sex identification is missing, the breakdown was as follows: 196 males and 343 females rated the desirability of the traits for an adult; 147 males and 317 females rated the traits for a man; 142 males and 266 females rated the traits for a woman. Discriminant analyses between males and females for each of the conditions were performed in order to determine whether there were meaningful differences in ratings due to the sex of the respondents. In the three analyses the differences between male and female raters were small, warranting pooling the data across sex. One interesting exception will be noted. There was a meaningful difference between male and female ratings of the desirability of the trait feminine for an adult, the mean rating by males being 3.69, and that by females 4.63. This result may be contrasted with the mean ratings of the two groups of the trait masculine for an adult: 5.20 and 5.09 by males and females, respectively.

ated with the 2 traits Feminine and Masculine in the first discriminant function are −.60 and .73, respectively, the absolute values of the coefficients associated with 44 other traits are less than .05, the remaining 14 traits having coefficients whose absolute values range from .05 to .12. The structure coefficients associated with the traits Feminine and Masculine are −.642 and .731, respectively, while those associated with the remaining traits are small except for 9 which are around .30.

The first trait to enter in the stepwise analysis was Masculine. This was followed by the trait Feminine. The remaining 58 traits add very little to the discrimination among the groups. Specifically, the overall λ (Lambda) associated with the 60 traits is .119, whereas that associated with the 2 traits Masculine and Feminine is .165. Also, the functions based on the 60 traits provide 89% of correct classification into the three groups, as compared with 87% correct classifications provided by the functions based on the traits Masculine and Feminine only. Looking back at the mean ratings of desirability (see Table 1), it is noted that the differences between the ratings of Masculine and Feminine for a man and for a woman far exceed the mean differences of the ratings of the remaining traits. Specifically, the mean ratings of Feminine for a woman and for a man are 6.17 and 1.39, respectively, and those of Masculine for a man and for a woman are 6.37 and 1.51, respectively.

The results of the present study are even clearer when one considers the discriminant analysis based on the ratings of desirability for a man and for a woman only—the two conditions used by Bem. The λ associated with the 60 traits is .108, while that associated with the traits Masculine and Feminine is .117. The use of the function based on the 60 traits provides 98.3% correct classification in the two groups, as compared with 97.7% accomplished by using the function based on the traits Masculine and Feminine only. Clearly, it is these two traits that carry the major burden of the discrimination between the two groups.

Factor analysis. As was noted earlier, the selection of traits for the BSRI and their classification into one of three categories—masculine, feminine, and neutral—was accomplished on the basis of tests of significance of the differences between the mean ratings of the desirability of each trait when applied to a man and when applied to a woman. Even if one were to accept this procedure, it is important to bear in mind that mean differences reveal nothing about the dimensions that underlie the relations among the ratings of the traits. The justification for treating a set of traits as a separate summated rating scale rests on the assumption that it is unidimensional. To the best of our knowledge, no attempt has been made by Bem, or by other researchers, to study the dimensions that underlie the ratings of desirability of the traits included in the BSRI.

In order to study the dimensionality of the BSRI, three separate factor analyses of the intercorrelations among the desirability ratings of the 60 traits when applied to a man, to a woman, or to an adult were performed.[2] Squared multiple correlations were used as initial estimates of the communalities. Both varimax orthogonal and oblique (delta = 0) rotations were used. The two solutions were very similar, and the correlations among the factors in the oblique solutions were close to zero. Consequently, only the orthogonal solutions are reported.

The rotated factor structures for the three referents are reported in Table 3. Three interpretable factors were retained in each analysis. Attempts to extract additional factors resulted in excessive fragmentation. It should be noted, however, that the three factor solutions account for about 80%, 81%, and 72% of the common factor variance for a man, a woman, and an adult, respectively.

Using a factor loading $\geq .40$ as criterion for meaningfulness, it will be noted that Factor 1 for the man and the adult referents and Factor 2, the woman referent, are very similar. The same 13 "feminine" traits and 8 "neutral" ones have meaningful loadings on

[2] Separate analyses were first performed for males and for females in each condition. Since the results were virtually the same, pooled analyses across sex within each condition are reported.

this factor. Among the traits with the highest loadings in the three solutions are the following: Compassionate, Sensitive to the needs of others, Understanding, Sympathetic, Warm, Tender, Gentle, Sincere, and Friendly. All express concern with, and positive affect toward, others. Consequently, the factor is named Interpersonal Sensitivity.

As will be noted from Table 3, several traits have meaningful loadings in only one of the solutions, the most notable being the trait Feminine, with a meaningful loading only when the referent is a woman. This is not surprising when one considers that all the items with high loadings on this factor have been rated relatively high in desirability for the three referents, except for the trait Feminine, which was rated high in desirability only when applied to a woman. Considering that the trait Feminine does not have a meaningful loading on the analogous factors associated with a man and an adult, and that it has the lowest of all the meaningful loadings on Factor 2 for a woman, it would be inappropriate to treat the traits that have high loadings on this factor as "feminine" traits, or to name the factor Femininity.

The second set of factors with similar patterns of loadings is composed of Factor 2 for a man and an adult, and Factor 1 for a woman. All the "masculine" traits have meaningful loadings for a man. Seventeen of these traits have meaningful loadings for an adult. Among the three traits that have no meaningful loadings on this factor is the trait Masculine, which is also the only trait that has no meaningful loading on Factor 1 for a woman. This latter exception is particularly notable considering that the meaningful loadings for a woman on Factor 1 are generally much larger than the loadings of the same traits on the respective factors for a man and for an adult. Moreover, while the loadings for the remaining 40 traits are low on Factor 2 for a man and for an adult, there is a trend toward bipolarity in Factor 1 when the referent is a woman. Note, for example, the negative loadings on this factor for the traits Yielding, Flatterable, Soft-spoken, Childlike, Conventional. The relative strength of this factor in the three solutions can be discerned from its eigenvalue, which is 5.77 for an adult, 8.12 for a man, and 13.43 for a woman.

The traits with the highest loadings on this factor for the three solutions are the following: Assertive, Forceful, Has leadership abilities, Acts as leader, Ambitious, Strong personality. The factor may be named Assertiveness or Instrumentality. Note, again, that the trait Masculine has a meaningful loading only when the referent is a man. Consequently, it would be a misnomer to name this factor Masculinity. (See Johnson, 1975, for a discussion that questions the validity of equating dependence and expressiveness with femininity, and equating independence, instrumentality, and assertiveness with masculinity.)

The third set of factors with similar patterns of factor loadings is composed of Factor 3 in the three solutions. Two of the "feminine" traits, Gullible and Childlike, have meaningful loadings in the three solutions. In addition, the trait Shy has a meaningful loading for a woman, and Flatterable for a man. Of the 10 "neutral" traits that are negative, 8 have meaningful loadings on this factor in the three solutions. Among traits with the highest loadings are Jealous, Secretive, Conceited, Gullible, and Childlike, all of which are probably best captured by the label Immaturity.

In sum, there is no evidence that the traits on the BSRI comprise three subsets of Masculinity, Femininity, and Social Desirability. While most of the "masculine" traits comprise a single factor, it appears that it would be most appropriate to refer to it as Instrumentality or Assertiveness. Moreover, it should be noted that this factor reflects a relatively narrow domain, as it is composed of some traits that are almost synonymous and others that are very close in meaning (e.g., Has leadership abilities and Acts as a leader; Self-reliant, Self-sufficient, and Independent).

The remaining two factors are each composed of a mixture of "feminine" and "neutral" traits. The distinction between the two factors is that one is composed of traits considered generally desirable for the three referents, whereas the other consists of traits considered relatively undesirable for the three

Table 3
Trait Desirability for an Adult, for a Man, and for a Woman, Four-Factor Solution, Orthogonal Rotation

[a] To facilitate reading and interpretation, traits have been grouped by scale rather than presented as they appear on the Bem Sex Role Inventory. Thus, Traits 1–20 are considered by Bem to be masculine; Traits 21–40, feminine; and Traits 41–60, neutral.

referents. The first was named Interpersonal Sensitivity, and the second, Immaturity.

Basically, the same factor structure is apparent in the three solutions, indicating that the crucial aspects in the rating of desirability of the traits is not the referent to which they are applied, but the respondents' conceptions of which traits are part of the same domain. A plausible explanation of the results could be made within the context of implicit personality theory (Schneider, 1973). The specific theory and the specific names of the factors notwithstanding, the results of this study indictate that it is inappropriate to treat the 20 "feminine" traits and the 20 "neutral" ones as two separate unidimensional sets.

Finally, it is obvious that one cannot obtain from a factor analysis more than one puts into it. Bearing in mind the approach in the selection of traits for the BSRI, it is not surprising that various dimensions and traits considered by other researchers as aspects of the domains of masculinity or femininity do not appear at all on the BSRI (see, for example, Bryson & Corey, 1977; Parker, 1969).

Study 2: Self-Ratings

This study was designed to investigate the pattern of responses to the BSRI traits, and the dimensions underlying the relations among them, when the instrument is used for self-rating. It should be noted at the outset that since the BSRI is a self-report inventory, it is subject to the limitations and deficiencies associated with such inventories, particularly those designed to measure self-concept (see, for example, Edwards, 1970; Messick, 1963; Wiggins, 1973; Wylie, 1968, 1974).

Only the 20 "masculine" and the 20 "feminine" traits were used in this study, because that is the form most often used in research related to sex roles, and because the dubious nature of the "neutral" traits was amply demonstrated in Study 1. A total of 571 graduate students of education attending one of two universities in New York City responded to the BSRI using Bem's directions.

Descriptive Statistics

Means and standard deviations for the 40 items for males and females are reported in Table 4. The most important thing to be noted is the general similarity of the mean ratings for males and for females. Except for the very large differences in the mean ratings of the traits Masculine (5.89 and 2.02 for males and females, respectively) and Feminine (5.85 and 2.09 for females and males, respectively), and the difference of 1.08 between the mean ratings of the trait Athletic, all other differences between the mean ratings of males and females are small, ranging (in absolute value) from .01 to .47, with a median of .16. The similarity of the ratings can also

Table 4

Note. *ns* = 171 (males) and 400 (females). BSRI = Bem Sex Role Inventory. Traits 1–20 are considered by Bem to be masculine and Traits 21–40, feminine.

be seen when one compares the overall mean ratings for males and females on Masculinity and Femininity, in which the traits Masculine and Feminine are included, and mean ratings in which those two traits are excluded. When the trait Masculine is included, the overall mean ratings of Masculinity for males and females, respectively, are 5.30 and 4.95, a difference of .35. When the trait Masculine is excluded, the respective means for males and females are 5.27 and 5.09, a difference of .18, or about half of the original difference. The overall mean ratings of Femininity, with the trait Feminine included, are 5.21 and 4.89 for females and males, respectively, the difference being .32. When the trait Feminine is excluded, the means for females and males are 5.17 and 5.03, respectively, a difference of .14, or less than half of the original difference.

From the overall mean ratings, it is clear that, on the average, both males and females indicate that "it is often true" (a rating of 5) that the traits in question describe them. This is even more pronounced when one excludes from consideration the traits Masculine and Feminine and the few traits that have been shown to be low in desirability (e.g., Gullible, Childlike). Since most of the traits have been rated toward the desirable end of the continuum when applied to an adult (see Table 1), it is conceivable that both males and females respond to the BSRI in a socially desirable manner or, as Smith (1968) has put it, with a "bias toward thinking as well of oneself as one can get away with" (p. 368). The available data cannot shed further light on this issue. It will be noted, however, that in a study by Parker and Veldman (1969), the traits Cheerful, Loyal, Sympathetic, Warm, and Gentle are part of a Social Desirability factor. Also, except for one or two traits, all the traits common to the BSRI and the Anderson (1968) list have been rated high on likability in several studies.

Lest one think that the relatively high mean ratings are unique to the present study, it is noted that other researchers have obtained similar results in the mean ratings of Masculinity and Femininity (cf. Bem, 1974, 1977). Since neither Bem nor other research-

ers report mean ratings on individual traits, more detailed comparisons are precluded.

Discriminant function analysis. Using overall mean ratings, Bem (1974) demonstrated that males score significantly higher than females on Masculinity, and that females score significantly higher than males on Femininity. If, as it appears, this was intended to lend support to the validity of the scales, several problems ensue, the most important being that Bem's contention that a person may be both masculine and feminine seems incompatible with the use of sex differences on Masculinity and Femininity as evidence of scale validity. This is particularly problematic when one uses groups that may be nonrepresentative of any population of males and females.

In any case, since Bem does not provide any information about mean ratings of individual traits, it is not possible to tell how much of the difference between males and females was due to the differences in the self-ratings on the traits Masculine and Feminine. It was shown above that the ratings on these two traits accounted for about half of the mean differences between males and females on Masculinity and on Femininity.

To further illustrate the relative potency of the traits Masculine and Feminine and that of the remaining 38 traits to discriminate between males and females, the responses of the two groups to the 40 traits were subjected to a stepwise discriminant function analysis. The findings are summarized in Table 5. Note that the λ associated with the 40 traits is .212 and the λ associated with the 2 traits Masculine and Feminine only is .241. Stated differently, the R^2 of the regression of group membership (male–female coded as a dummy variable) on the 40 traits is .788, while that on only the 2 traits Masculine and Feminine is .759. While 96.7% of the males and females are correctly classified on the basis of the full function, 93.5% of them are correctly classified by using the function based on the traits Masculine and Feminine. To further highlight the findings, it will be noted that the standardized coefficients associated with the traits Feminine and Masculine in the full function are −.70 and .55, respectively. Of the remaining traits, 32 have coefficients of <.10, and six have coefficients between .10 and .15. Probably even more revealing are the structure coefficients, which for the traits Feminine and Masculine are −.80 and .76, respectively. Except for the trait Athletic, whose structure coefficient is .14, and the trait Tender, whose structure coefficient is −.10, all the remaining traits have structure coefficients of <.10, with most being close to zero.

In sum, all the indices strongly support the notion that the discrimination between males and females is almost exclusively due to their self-ratings on the two traits Masculine and Feminine. Stated differently, knowledge of respondents' self-ratings on the remaining 38 traits adds little to the knowledge obtained from their ratings on Masculine and Feminine. Not surprisingly, males rate themselves high on Masculine and low on Feminine. The converse is true for females.

Factor analysis. It was stated earlier that we have not found any published reports of factor analyses of the desirability ratings of the BSRI traits. We did find one published study in which self-ratings on the BSRI were

Table 5
Discriminant Analysis of Trait Self-Ratings for Males and for Females

Traits	R^2	Λ	*df*	χ^2	% correct classification	Centroids
40	.788	.212	40	850.47	96.7	−1.26 2.94
Masculine	.759	.241	2	808.24	93.5	−2.71
Feminine						1.16

Note. *ns* = 171 (males) and 400 (females).

factor analyzed (Gaudreau, 1977). This study suffers from several methodological shortcomings. Not only were males and females used in a single analysis but also the subjects came from widely diverse groups (i.e., clerical workers, supervisors, middle managers, executives, police officers, and housewives). Warnings against inducing spurious correlations among variables by using heterogeneous groups have been sounded frequently throughout the brief history of social science research. Spearman (1904), for example, criticized researchers who "have purposely thrown together subjects of all sorts and ages, and thus have gone out of their way to invite fallacious elements into their work" (p. 223). Guilford (1952) elaborated on the dangers of using diverse groups in a single-factor analysis.

Another flaw in Gaudreau's (1977) analysis is that in addition to the individual traits, she included the scores on Masculinity, Femininity, and Androgyny (i.e., the discrepancy between Masculinity and Femininity), thus introducing three linear and experimental dependencies that may lead to artifactors rather than factors (see, for example, Gorsuch, 1974, pp. 267–268; Guilford, 1952). Because of these problems Gaudreau's findings will not be discussed.

In the present study, separate principal-axes factor analyses were performed for the male and female groups. Squared multiple correlations were used as initial estimates of the communalities. Both varimax orthogonal and oblique (delta = 0) rotations were used. Since the solutions were very similar, only the orthogonal ones are reported.

Four interpretable factors emerged from each analysis, accounting for about 83% and 73% of the common-factor variance for females and males, respectively. Extraction of a fifth factor for the males resulted in accounting for an additional 5% of the common-factor variance, but in a less interpretable factor structure. The two orthogonally rotated four-factor solutions are reported in Table 6.

Looking first at the factor structure for females and treating loadings of $\geq .40$ as meaningful, 17 traits load meaningfully on Factor 1. All but one are what Bem classifies as masculine traits, the exception being the "feminine" trait Shy, which loads negatively on this factor. The highest loadings are associated with the following traits: Assertive, Forceful, Acts as leader, Has leadership abilities, Strong personality, Dominant, and Aggressive. It is clearly an assertiveness factor. Factor 2 has 12 traits with meaningful loadings, all of which are classified as feminine by Bem. The traits with the highest loadings are Compassionate, Tender, Understanding, Sympathetic, Sensitive to the needs of others, and Gentle, all reflecting interpersonal sensitivity. Factor 3 is bipolar with three traits (Self-reliant, Independent, and Self-sufficient) loading positively, and two traits (Gullible and Childlike) loading negatively. This cluster of traits appears to reflect one's feelings of self-sufficiency; that is, individuals who perceive themselves as being self-sufficient, or relying on their own resources, quite naturally tend also to perceive themselves as not being gullible and childlike. Factor 4 is bipolar with only two traits having meaningful loadings on it. Feminine, with a positive loading, and Masculine, with a negative loading. Bem's contention that Masculinity and Femininity are orthogonal dimensions notwithstanding, females who rate themselves high on Feminine tend to rate themselves low on Masculine, regardless of their self-ratings on the remaining traits.

Compared with the females, the males tend to make a greater and stronger differentiation between assertiveness and self-sufficiency as reflected by Factors 2 and 3, respectively. Note that, as in the solution for females, the trait Shy has a negative loading on the Assertiveness factor. Also, Loyal, which is presumably a feminine trait, has a meaningful loading on the Self-sufficiency factor. Factor 1 for males is similar to Factor 2 for females, except that the loadings in the former tend to be higher than in the latter (eigenvalues of 5.46 and 4.90, respectively). Eleven of the "feminine" traits have meaningful loadings on this factor, which clearly reflects the notion of interpersonal sensitivity. As in the solution for the females, Factor 4 is bipolar. But it differs from the corresponding factor for females in that, in addition to the trait Masculine loading positively and the trait Feminine

λ	6.93	4.90	1.67	1.07	5.46	4.46	3.69	1.79

Note. Factor loadings ≥.40 are in boldface. *ns* = 400 (females) and 171 (males). BSRI = Bem Sex Role Inventory.
[a] To facilitate reading and interpretation, traits have been grouped by scale rather than as they appear on the BSRI. Thus, Traits 1–20 are considered by Bem to be masculine, and Traits 21–40, feminine.

negatively, the traits Gullible and Childlike also have negative loadings. Males who rate themselves high on Masculine tend to rate themselves low on Feminine as well as Gullible and Childlike, implying that they perceive these traits as related to their conception of Feminine. It will be recalled that Gullible and Childlike had negative loadings on the Self-sufficiency factor in the solution for females.

In sum, the factor analyses of self-ratings

for males and females do not reflect the dimensions of masculinity and femininity proposed by Bem. Not only did four factors emerge in each solution, but also, despite some similarities, they are sufficienty different from each other to lead one to believe that the patterns of self-ratings for males and for females differ. The fact that the traits Masculine and Feminine describe a separate bipolar factor also casts doubt on the validity of the classification of the remaining items as masculine and feminine. It will also be noted that some traits (e.g., Yielding, Soft-spoken) did not have meaningful loadings in either of the solutions.

Because some researchers seem to consider internal consistency reliability as evidence of the unidimensionality of summated rating scales, we present some reliability data on the Femininity scale to demonstrate the dubious nature of this approach. In the present study, the alphas for the Femininity scale (consisting of the 20 "feminine" items) are .79 and .77 for females and males, respectively. Contrast these with the alphas of .87 and .89 for females and males, respectively, on the 11 items with meaningful loadings on the Interpersonal Sensitivity factor (see Table 6, Factor 2 for females and Factor 1 for males; the trait Feminine, which has a meaningful loading on this factor for females only, was excluded from this analysis for comparative purposes).

It would be interesting to compare the factor structures obtained under the conditions of self-ratings with those obtained under the conditions of desirability ratings (Study 1). It should be noted, however, that the two studies used different subjects and that Study 1 included also the "neutral" traits. Nevertheless, on the basis of the differences in the nature of self-ratings and desirability ratings, and on the basis of the overall pattern of the two sets of factor structures, it seems plausible to speculate that the dimensions that underlie trait ratings differ when the task is to rate oneself and when it is to rate the desirability of the traits for an abstract referent. Assuming that similar findings are obtained in future research, one would have to question the validity of arriving at subscales for self-ratings on the basis of analysis of desirability ratings.

Discussion

Bem's effort to construct measures of masculinity and femininity was destined to fail, as it was based solely on an empirical approach in which trait selection was determined by a multitude of nonindependent univariate tests of significance. It is not surprising that some of the traits designated as sex related by Bem are considered neutral, and vice versa, by other researchers, who have resorted to different empirical approaches in their search for sex-related traits. The absence of theoretical definitions of the constructs precludes attempts to determine whether or not a given set of traits is representative of a given domain. How can one assess the validity of a measure when the construct it is supposed to be measuring is undefined? The present discussion is necessarily limited to a consideration of the properties of the BSRI regardless of one's definitions of sex roles.

It will be recalled that Bem's sole criterion for the designation of a trait as sex related was whether or not there was a significant difference in the ratings of its desirability for a man and for a woman. As was demonstrated in Study 1, this approach yielded 20 "masculine" traits which are all positive, or relatively high on desirability, and 20 "feminine" traits, some of which are negative even when the referent is a woman. This, of course, has implications for the total scores on Masculinity and Femininity, in view of people's general tendency to attribute to themselves positive traits, and their reluctance to attribute to themselves negative traits, when they respond to a self-report instrument. This problem is particularly serious because the difference between the scores on Masculinity and Femininity is used to arrive at an Androgyny score.

Before dealing with the issues of androgyny, however, it is important to note that no attempt was made by Bem, or other researchers using the BSRI, to study the dimensions that underlie the ratings of the desirability of the BSRI traits. It was demonstrated in Study 1 that the factor structure of the ratings of trait desirability is not consistent with the

BSRI trait classification. While most of the "masculine" traits have meaningful loadings on a single factor, reflecting a narrow domain of assertiveness, the "feminine" and the "neutral" traits are indistinguishable from each other, and break down into two factors: one consisting of positive traits reflecting interpersonal sensitivity; the other being composed of negative traits reflecting emotional immaturity. Consequently, it is inappropriate to treat the 20 "feminine" traits as a single summated rating scale.

The situation becomes even more complicated when one recalls that the factor structure of self-ratings (Study 2) was more complex in that the "masculine" items also split into two factors. Moreover, the factor structure for females differed from the one for males.

The above noted findings are sufficient to reject Bem's operational definition of androgyny solely on empirical grounds. Since, however, the popularity of the BSRI is probably due primarily to the Androgyny score that it presumably provides, it is of interest to sketch the metamorphosis that the operational definition of androgyny has undergone during its brief history. Except for indicating that being androgynous means being "*both* masculine and feminine, *both* assertive and yielding, *both* instrumental and expressive" (Bem, 1974, p. 555), Bem provides no discussion of androgyny. Instead, it is operationally defined on the basis of a test of significance between the means of Masculinity and Femininity, treating the self-ratings of one individual on 40 traits as being independent of each other. It seems unnecessary to discuss the problems in such an approach, as this has already been done by Strahan (1975). Nor is it necessary to discuss the methodological problems attendant on the use of difference scores, as detailed discussions are available (e.g., Harris, 1963). It will only be pointed out that the use of a difference score as a definition of a construct is highly questionable (see, for example, Cronbach, 1958; Cronbach & Furby, 1970).

Responding to criticisms (e.g., Spence, Helmreich, & Stapp, 1975; Strahan, 1975) that her operational definition of androgyny does not distinguish between different kinds of the same numerical discrepancy between Masculinity and Femininity (e.g., high–high, average–average, low–low), Bem proposed that median splits be used instead. According to the new definition, people who are above the median on both scales are classified as androgynous; those who are above the median on Masculinity and below the median on Femininity are classified as masculine; people who are above the median on Femininity and below the median on Masculinity are classified as feminine; and those below the median on both scales are considered undifferentiated. This is probably the crudest and the least useful method for arriving at a typology (for a review of available methods see Bailey, 1974). When using median splits one runs the risk of classifying some of the people whose scores on both scales are relatively similar as being different types, and of classifying some whose scores are relatively dissimilar as being of the same type. If, in addition, it is noted that all the groups used in studies with the BSRI were groups of convenience and not samples of any defined population, it becomes evident that a person may be classified as being one type or another depending upon the aggregate of people to which he, or she, is considered to belong because the BSRI was administered to them (e.g., introductory psychology classes). Finally, the use of median splits is unwarranted in view of the factorial complexity of the scales.

In a recent discussion of the relative merits of difference scores and median splits, Bem (1977) relies again on statistical tests of significance as the sole criterion. Using an assortment of scales (e.g., Attitudes Toward Women, Internal–External Locus of Control, Machiavellianism, Self-Esteem), Bem tested whether high–high individuals differed significantly from low–low individuals on each. Having found significant differences on some scales, but not on others, she concluded that a distinction between high–high and low–low was warranted, though she acknowledged that she was unable to specify the conditions under which the high–high will differ from the low–low. Is one to deduce that sometimes

high–high and low–low are the same kind of androgynous people, and sometimes they are different (androgynous?) types, though it is not possible to say when?

Bem (1977) concludes her discussion by stating, "Finally, we urge investigators to further analyze their data without categorizing individual subjects in any way, i.e., through the use of multiple regression techniques" (p. 204). While endorsing what appears to be a suggestion to conduct studies within the framework of trait–treatment interactions, one cannot help wondering: Where has androgyny gone?

Postscript

We confine this comment on Bem's (1979) reply to the present article to the question of the theory behind the construction of the BSRI. Nowhere in her earlier statements regarding the construction of the BSRI (e.g., Bem, 1974) were we able to find an allusion to the theory of sex roles that is said by Bem (1979) to be the basis for the BSRI. Bem does make reference to statements by other people about possible motivational processes of sex-typed individuals. But nowhere does she present "a theory about both the cognitive processing and the motivational dynamics of sex-typed and androgynous individuals" (Bem, 1979, p. 1048). Quite the contrary, Bem

has stated, "My hypotheses have derived from *no* formal theory" (Bem, Note 2, p. 1, italics added). In our opinion, the rationale presented in Bem's (1979) reply to this article does not constitute even a rudimentary theory. Asserting, as Bem does, that some individuals are motivated to conform to sex-typed cultural norms and that others are not motivated to do so, or that some individuals are "consistent" and others are "inconsistent", is tautological, unless one articulates a theoretical explanation for such phenomena.

Thus, in our opinion, it is Bem's approach to scale construction, *not* the culture, that "has *clustered* a quite heterogeneous collection of attributes into two mutually exclusive categories" (Bem, 1979, p. 1048, italics added). It is Bem, not the culture, that "groups a hodgepodge of attributes into a category *it calls* 'femininity' or 'masculinity' " (Bem, 1979, p.1049, italics added). And it is Bem who treats a hodgepodge of items as if it comprised a unidimentional scale. Bem maintains that her "theory deliberately does not specify the particular contents of these definitions, however, because these will vary from culture to culture" (Bem, 1979, p. 1049) and because hers is a theory of "process" not of "content." How, then, does one reconcile this orientation with the approach used by Bem in the revision of the BSRI (Bem, 1979, p. 1051) in which items are eliminated because their correlations with the total score are low, or because they load on separate factors? Seeking to determine which items are "clustered," Bem appropriately resorts to some of the same methods whose absence in the construction of the original BSRI we have criticized. In sum, we do not see how the retained items in the short BSRI reflect a theory of "process" that is not enunciated.

Psychological Androgyny: A Case of Mistaken Identity?

Anne Locksley
New York University

Mary Ellen Colten
University of Michigan

This article critically discusses theoretical and methodological issues raised by psychological androgyny research and theory. A number of problematic assumptions shared by this approach and the previous masculinity/femininity approach are detailed. The first part of the article considers whether inventories devised to tap general sex stereotypes should be used as individual personality measures. Alternative forms of cognitive structures, linking sex, other person features, and behavioral rules, are described and hypothesized to have sex-differentiating effects on behavior. The second part of the article discusses problems created by the persistent use of indicators of adaptation and mental health as criterion variables in research on sex identity and sex roles. It is suggested that a psychological theory of sex identity and sex roles should recognize the fact that sex is a structural feature of situations and of ongoing organizations of life experience. In a society in which sex plays a role in the very structuration of experience, the notion of psychological androgyny, with its implication of freedom from sex-related social and biological effects on personality and behavior, is arbitrary.

Reviews of 40 years of psychological research and theory about masculinity/femininity (Constantinople, 1973; Harrison, 1975; Maccoby & Jacklin, 1974; Pleck, 1975, 1976) reveal that Terman and Miles's (1936) original formulation of the masculinity/femininity construct initiated a line of research that consistently failed to provide a coherent, reliable, empirical basis for psychological theories of sex identity. Indeed, the presuppositions of this research were never substantiated. Recently, the concept of psychological androgyny (Bem, 1974, 1975, 1976; Block, 1973; Heilbrun, 1973; Spence & Helmreich, 1978; Spence, Helmreich, & Stapp, 1974, 1975; Bem, Note 1) has emerged in the wake of masculinity/femininity research. It has already been hailed as an exemplar for a new paradigm for psychological research on sex identity (cf. Harrison, 1975; Kaplan & Bean, 1976; Pleck, 1975, 1976; Rebecca, Hefner, & Oleshansky, 1976).

At first glance, the concept of psychological androgyny is very appealing. The concept, and the theory in which it is nested, seems to be saying not only that there is no intrinsic link between one's anatomical sex and one's behavior and interests, but also that people whose personalities fail to conform to sex-role standards are better off for it. However, research and theory about psychological androgyny deserve more than a first glance for their proper evaluation. The politicization of the argument has tended to obscure the fact that it makes specifically psychological assertions about the nature of sex identity, definitions of masculinity and femininity, and appropriate means of measuring these phenomena. The validity of these psychological assumptions and techniques for measurement should be assessed on scientific as well as political grounds. After all, the general area of

The first author is grateful for the facilities permitting the preparation of the final draft of this manuscript that were generously provided by the Laboratory for Research in Social Relations at the University of Minnesota.

sex roles and sex differences in psychology can only benefit from testing the theoretical and methodological mettle of what has already been acclaimed as an important new contribution to the field.

Accordingly, the present article is intended to contribute to a reflective and critical analysis of psychological androgyny research and theory. It should be noted at the outset that the primary focus of this paper is on the logic of psychological androgyny research, as expressed in theoretical formulations and methodological practices. We will not address psychometric issues raised by existing measures of psychological androgyny, except when they are indicative of the conceptualization of the phenomena in question. Thus recent studies of the instability of Bem's (1974) item-selection procedure (cf. Edwards & Ashworth, 1977; Walkup & Abbott, 1978) or of the Bem Sex Role Inventory (BSRI) factor structure (Gaudreau, 1977; Moreland et al., 1978) will not be discussed. Nor will other purely psychometric considerations, such as the absence of homogeneity across classes of trait terms (cf. Hogan, DeSoto, & Solano, 1977) on the BSRI, (cf. also Strahan, 1975), be explored. The fundamental issues addressed here are (a) the feasibility of using inventories developed to tap general perceptions of aggregate differences as measures of individual differences and (b) the appropriateness of a traditional individual-differences approach to the phenomena of sex roles, sex differences in personality or behavior, and sex identity. It will become apparent that psychological androgyny research and theory, far from constituting a radical departure, share a number of problematic assumptions with masculinity/femininity research and theory. We discuss some of these problems with the hope of encouraging a better approach to the phenomena of sex roles, sex differences in personality, and sex identity.

Definition of Psychological Androgyny

The concept of psychological androgyny has been operationally defined in differing ways, though there is a general consensus about the properties that define an androgynous person. These properties are best understood in relation to the earlier formulation of masculinity/femininity. The various masculinity/femininity measures (Gough, 1952; Guilford & Guilford, 1936; Hathaway & McKinley, 1951; Strong, 1936; Terman & Miles, 1936) had all been constructed with the assumption that masculinity and femininity were opposite poles of a single dimension; thus the less masculine a given respondent's score, the more feminine the respondent was deemed to be, ipso facto. In contrast, the concept of psychological androgyny presupposes that masculinity and femininity are orthogonal personality constructs, making it possible to categorize respondents on the basis of their scores on both masculinity and femininity scales.

Psychological androgyny has been defined simply as a function of masculinity and femininity scores. Currently two scales are widely used in psychological androgyny research: the Bem Sex Role Inventory (BSRI), developed by Bem (1974), and the Personal Attributes Questionnaire (PAQ), developed by Spence, Helmreich, and Stapp (1974) with items culled from the Sex Role Stereotype Questionnaire (Rosenkrantz, Vogel, Bee, Broverman, & Broverman, 1968). Bem originally used the BSRI to categorize respondents into three groups: masculine, feminine, and androgynous. However, the Spence group argued that truly androgynous people are those who endorse both masculine and feminine traits, while those who endorse neither are undifferentiated with respect to masculinity and femininity. Accordingly, Bem (1977) explored the utility of this distinction. Although her reanalyses of data from earlier experimental studies, and her investigation of relationships between sex type and other personality constructs, produced equivocal results, she concluded that the distinction between undifferentiated and androgynous respondents is warranted. So psychological androgyny is the presence of both masculinity and femininity. In turn, masculinity and femininity are defined as additive combinations of trait terms judged to be significantly more desirable for, or more characteristic of, each sex relative to the other.

Bem and Spence and Helmreich are in accord with respect to the essential content of

the masculinity and femininity constructs. Both consider femininity to involve nurturance, expressivity, and empathy, and masculinity to involve agency, instrumentality, and dominance. However, they interpret scores on their own instruments somewhat differently. Bem deliberately invokes cognitive and dispositional processes for interpreting responses to the BSRI. At one point she writes that cross-situational consistency in behavior can be attributed to a "motivational disturbance" that "causes a person to respond to dissimilar situations *as if* they were equivalent" because she or he "is defensively motivated to maintain some sort of image" (Note 1, p. 8). Highly "sex-typed" persons are seen to be defensively motivated in this sense. Thus Bem presents the BSRI as a measure of the "degree of sex-role stereotyping in the person's self-concept" (1976, p. 51).

In contrast, Spence and Helmreich avoid appeals to cognitive or motivational processes and argue that responses to the PAQ can be understood as relatively veridical assessments of individuals' repertoires of traits or personality characteristics (cf. Spence & Helmreich, 1978, pp. 14–16). They are especially committed to distinguishing masculinity and femininity as personality constructs from sex role-related behavior, as well as from dispositions to actualize concepts of masculinity and femininity.

From our perspective, the theoretical and methodological similarities of the two bodies of work outweigh their differences and justify their joint treatment. Most of the criticisms to be presented here are intended to speak both to Bem's and to Spence and Helmreich's work on psychological androgyny. However, as a result of their differing interpretations of their scales, some criticisms will refer only to Bems work,[1] and other criticisms only to Spence and Helmreich's work. In such cases the referent will be explicit.

Problems With the Conceptualization and Measurement of Psychological Androgyny

The development and labeling of any personality typology involve claims of reference and of identity. The investigator in effect asserts that all persons falling within each category of the typology can be considered as equivalent, at least with respect to the quality identified by the category title. The strategy by which the typology or measure is constructed essentially represents the logic of these claims. The labeling of the typology, particularly when appropriating terms current in ordinary discourse, conveys the nature of the quality or construct at issue and thereby evokes commonly associated expectations and assumptions. This section considers the logic governing the development and application of the BSRI and the PAQ, traces the origin of that logic in masculinity/femininity research, and seriously questions its validity.

Whether defining masculinity and femininity as opposite ends of a continuum or as orthogonal dimensional constructs, psychologists have invariably derived their content from aggregate differentiation of the two sexes,

---

[1] Because Bem invokes cognitive and dispositional processes when interpreting responses to the BSRI, the burden of proof, as it were, is heavier for her than for Spence and Helmreich. Bem wants to interpret item endorsement as indicative of the extent to which sex stereotypes have been internalized and consequently control one's behavior, proscribing and prescribing various acts. However, the nature of the BSRI items and the manner of the administration of the BSRI do not warrant such an inference. For example, consider two items on the BSRI Masculinity scale: "Acts as a leader" and "has leadership abilities." In order to know whether or not one has leadership abilities, one has to have been in situations in which such a position was accessible. It hardly needs to be pointed out that tremendous discrimination against women's assumption of leadership positions is a pervasive feature of our society. Endorsement of such an item, or lack thereof, may be a function of experiences and of the cumulative effects of those experiences resulting from a number of causes other than identification with a sex stereotype. In general, responses may reflect behavior induced by systematic situational factors as well as behavior indicative of personal dispositions. The lack of homogeneity (cf. Hogan et al., 1977) among the trait terms also undermines the assumption that exclusive endorsement of masculinity items or exclusive endorsement of femininity items necessarily reflects a global underlying disposition to emulate masculine or feminine stereotypes. Factor analyses (Gaudreau, 1977; Moreland et al., 1978) have produced four factors more internally consistent than the original three BSRI scales, further weakening the assumption of unidimensional constructs conforming to the original labels.

biologically defined, and have created constructs subsequently applied to members of either sex. Masculinity/femininity research was generally based on the assumption that sex type is a function of behaviors or attributes significantly more characteristic of one sex than of the other. Sex-differing attributes were established empirically; sex differences in response constituted the criterion for item selection in developing the masculinity/femininity scales.

Psychological androgyny researchers differ from masculinity/femininity researchers not only in treating masculinity and femininity as orthogonal constructs but also in relying on general perceptions of aggregate sex differences in personality attributes. Items for both the BSRI and the PAQ masculinity and femininity scales were selected because they were judged, on the average, to be differentially desirable or characteristic of the typical man and the typical woman. This concept of masculinity and femininity, as composites of attributes distinguishing males from females in general, has been a persistent feature of sex-stereotype research (e.g., Broverman, Vogel, Broverman, Clarkson, & Rosenkrantz, 1972; McKee & Sherriffs, 1957, 1959; Rosenkrantz et al., 1968; Sherriffs & Jarrett, 1953; Sherriffs & McKee, 1957). Indeed, the BSRI and the PAQ are constructed in exactly the same manner as the sex-stereotype scales. The psychological androgyny researchers have assumed that sex type is a function of covariation between individual traits and traits popularly thought to be differentially desirable or typical of men and of women.

The distinction between actual and stereotypically perceived sex differences is an important one. Obviously the effect on behavior of generally held notions about personality covariates of sex may be quite different from the effect of anatomical sex on behavior. There may be sex differences in behavior caused by social or biological factors that are not perceived to be a function of sex and that are consequently not even partially attributable to the press of differential socialization practices or normative expectations. The two sorts of effects on behavior were confounded in masculinity/femininity research by the use of sex differences in item response as the criterion for item selection. In addition, the restriction of scale content to items perceived to be linked to sex forces consideration of the cognitive mediation of a sense of self by concepts connecting sex and other attributes, and of the effects of these concepts on behavior. The reliance on self-report for the measurement of individual differences further underscores the need for recognizing the role of cognitive aspects of sex typing or sex identity on sex differentiation in behavior.

But like the masculinity/femininity researchers, the psychological androgyny researchers use personality inventories developed around aggregate distinctions between the categories of biological sex to measure individual differences in personality regardless of biological sex. This procedure raises two basic theoretical and methodological questions. First, if the intent is to define and measure individual differences in masculinity and femininity, should the definition and measurement of these constructs be based on stereotypically perceived aggregate sex differences? Second, can an inventory developed to tap beliefs about aggregate sex differences be used as a measure of individual differences? Specifically, can the sense provided by the context in which the measure is developed be sustained in the context of its application?

Limitations of the Stereotypic Conception of Masculinity and Femininity

The rationale for deriving the BSRI and the PAQ from sex stereotypes is based on the assumption that different frequencies of attributing adjectives to the typical woman or the typical man indicate beliefs about covariates of sex. The findings of sex-stereotype research do not necessarily support this assumption. Because sex segregation in family and work roles is a widespread feature of American society, those adjectives that meet the criterion may be linked to prototypically female and male family and work roles rather than to sex per se. The evidence suggests that this might be the case. Clifton, McGrath, and Wick (1976) asked a sample of respondents to check those adjectives, from a list of 153, that describe the typical housewife, bunny,

club woman, career woman, and woman athlete. They reasoned that if a general stereotype of women existed, then similar clusters of adjectives should be used across all roles. Instead, they found a surprisingly low commonality of adjectives used across all roles. Indeed, only one adjective was used to describe each of the five types of woman: active. The adjectives used to describe the typical housewife were very similar to those found on the BSRI and the PAQ femininity scales. However, none of the adjectives used to describe bunny appear on these scales. The other three roles, club woman, career woman, and woman athlete, were all described with a preponderance of adjectives similar to those on the BSRI and the PAQ masculinity scales.

Inspection of the content of the PAQ and the BSRI further corroborates the premise that respondents ideas of characteristics generally distinguishing males and females and their ideas of characteristics specific to highly sex-segregated roles (e.g., housewife/mother and career man) may be confounded. It is not difficult to derive traits of nurturance, empathy, and expressiveness from the American ideal of motherhood, or to derive traits of agency, instrumentality, and dominance from the American ideal of the father providing for his family.

Like all sex-stereotype scales developed to date, the BSRI and the PAQ development procedures left respondents with no choice but to try to convey the significance of nontrait person features with trait terms. The consequences may be misleading. For example, Johnson (1975) has pointed out that the instrumentality/expressiveness dichotomy is not a good indication of the masculinity/femininity dichotomy because traditionally female activities, such as mothering, require instrumental behavior in order to be carried out effectively. Nonetheless, the instrumentality/expressiveness dichotomy recurs consistently throughout the sex-stereotype literature and is the basis of the BSRI and the PAQ. We suspect that this distinction derives from the prototypical middle-class housewife who, as a result of present-day affluence, does not procure resources for the family. When the family unit is less affluent, mothering responsibilities often include actions that obtain resources needed for family survival. When trait terms are the only means by which respondents can distinguish females from males, the terms may be used to signify something other than their ordinarily understood meanings. Although the typical housewife may not work for money or use social networks to procure major survival resources, her actual behavior may require "agency" or "instrumentality," and her instrumentality is distinguishable from that of her husband not by adjectival characterizations of behavior but by the context in which it occurs and the purposes it serves. These observations suggest that the content of general sex stereotypes may be nothing other than reified personality characteristics associated with ideal representatives of adult, sex-segregated social roles.

The probable nonindependence of conceptions of prototypically sex-segregated social roles and conceptions of general covariates with sex has several problematic implications for psychological androgyny research and theory. To begin with, most psychological androgyny research has been conducted on college students and even on high school students. The variance in scores permitting the categorization of androgynous persons may indicate only the lack of press from the definitions and constraints of adult sex-segregated social roles rather than the absence of relevant sex-differentiated traits. In fact, the preoccupation of adolescents and young adults with sexuality and courtship suggests an alternative list of adjectives to that of the BSRI or the PAQ. Furthermore, Clifton et al.'s (1976) failure to obtain general stereotypes when information in addition to that of the stimulus person's sex was provided is corroborated by reflection on ordinary language rules. For example, we make discriminations based on such person features as age, sex, and kinship position when we characterize people with sex-related qualities. We may say, "The Marlboro man is the epitome of masculinity," but we don't say, "He's a masculine father," even though it is syntactically acceptable to do so. Similarly, we may characterize a man as effeminate, but not a woman. These observations suggest that general sex stereotypes may

be too global for interpreting and guiding behavior at the level of individual self-perception or self-direction.

The assumption that traits differentially attributed to the typical woman and the typical man retain their sex-associated character when used for self-description purposes is undermined by a recent series of experiments by Nisbett and Zukier (Note 2). They demonstrate that the impact of stereotypes on social inference and prediction is diluted by the presence of "nondiagnostic" information, that is, information unrelated to the stereotype. Obviously, personal experience provides a wealth of nondiagnostic information with respect to global sex stereotypes. The results of Nisbett and Zukier's studies suggest that global sex stereotypes are rarely activated for self-perception or self-description purposes. In fact it is probable that general sex stereotypes are most likely to have effects under either of the following conditions: (a) in situations comparable to those in which sex stereotypes are assessed, namely, in situations in which only the sex of the target person is known or in which sex is the most informative characteristic known, and (b) in situations in which sex is the salient factor distinguishing two persons and in which its general covariates are representative of the situational requisites. Support for the first condition is provided by studies of preferential hiring decisions. Blau and Jusenius (1976) show that sex discrimination in employment is most extensive at the port of entry for internal job ladders precisely because few other person features (e.g., dependability, companionability) relevant for long-term association are known. Support for the second condition is suggested by the popular recognition of the impact of childbirth and of parenting during early infancy on parents' acceptance of, and behavioral adherence to, sex stereotypes.

Psychological androgyny researchers define masculinity and femininity as stereotypically perceived composites of traits believed to differentiate the sexes on the average. However, if the intent is to use concepts of sex covariates at the individual level of analysis, in an effort to discern either the influence of these concepts on behavior or the presence and ramifications of those covariates, it may be more reasonable and effective to tap those concepts most pertinent for self-description and self-perception. Otherwise, psychological androgyny may reflect only the failure of the particular masculinity and femininity measures used to tap the most salient dimensions of sex differentiation in personality and behavior. Certainly the form and content of ideas of sex covariates have yet to be determined. They may be like disconnected sets of propositions (e.g., propositions about lesbians may be quite different from propositions about glamorous actresses); they may distinguish people on the basis of kinship categories or on the basis of traits; they may be embedded in concepts of settings or environments. Wittgenstein's (1958) notion of a family of concepts with varying criteria of family resemblances may be more appropriate here than the notion of a solitary and general sex stereotype. In any case, the determination of the nature of ordinary concepts linking sex, other attributes, and behavioral rules is important because of its ramifications for the types of predictions one would make about the effects of such concepts or cognitive structures on behavior.

Recent work in cognitive psychology offers hypotheses about the nature and structure of ideas of masculinity and femininity alternative to those presupposed by Bem and by Spence and Helmreich. The BSRI and PAQ development and scoring procedures attribute masculinity to an individual when all traits believed to be significantly more desirable for, or characteristic of, males rather than females are properties of that individual. The attribution of femininity follows a parallel logic. However, the structure of such concepts need not be so Aristotelian. For example, Rosch (1975) demonstrated that the structure of cognitive representations of categories can be of a prototypical sort. Such a category is represented by a particular object, called a good instance of the category, surrounded by other objects of decreasing similarity to the prototype and correspondingly decreasing degrees of membership. Analogously, popular ideas of what it is to be a woman and what it is to be a man may be represented by proto-

typical persona, or conceptual structures that cluster salient information definitive of a type or category of individuals. Unlike trait-dimensional summaries of people, person prototypes may cluster diverse types of information (e.g., physical appearance, occupation, social prestige, as well as behavioral dispositions and characteristics), including information about vivid, immediately perceptible person features. Such features may activate the prototype, causing the individual to generate numerous inferences about the stimulus person's probable behavioral dispositions in the absence of any information about their actual behavior (e.g., Snyder, Tanke, & Berscheid, 1977; Taylor & Crocker, Note 3). This type of reasoning can affect self-perception as well. For example, when the poet Maya Angelou was 15 years old, she decided that she must be a lesbian because, unlike her girlfriends, her breasts remained small, her hips narrow, and her voice deep (Angelou, 1971). For her, a boyish physique was as evocative of the category of lesbianism as homoerotic feelings.

Certainly the investigator retains the right to label operationally defined personological phenomena as she or he chooses. But should the scientific meaning of terms be arbitrary with respect to their ordinary sense? The term *psychological androgyny* clearly implies "of indeterminate sex, or not sex related." However, its scientific operationalization defines persons as androgynous only in relation to global sex stereotypes. Such persons may still be as influenced as sex-typed persons by concepts of sex-linked attributes, or may evidence sex-differentiated personality or behavioral qualities.

Methodological Problems of Using Sex Stereotypes for Individual-Difference Measures

The validity of transferring the sense provided by the context in which the BSRI and the PAQ were developed to the context in which they are administered can be questioned on certain methodological grounds. The conceptual and referential context in which judgments are made about the self is entirely different from the context in which judgments are made about such abstractions as the typical man and the typical woman.

To begin with, self-rating on an attribute entails comparison processes. When female respondents rate themselves, are they comparing themselves to their female peers, their peers of both sexes, to a general notion of the average woman, or to some specific exemplar of femininity? The same question can be asked regarding male respondents. For example, a woman may endorse "athletic" as a true description of herself because she is athletic relative to other women, although she may not be particularly athletic relative to most men. Similarly a man may endorse "compassionate" because he considers himself to be more compassionate than most men, though less compassionate than most women. Furthermore, the behaviors referred to by these terms may not be the same for men as for women. The compassionate man may be thinking of his indignation over inequities and injustices in the world, whereas the compassionate woman may be thinking of her empathy for the problems of her friends. Endorsement of the same items may thus conceal sex differences, again raising the question of the validity of the behavioral reflections of a label such as *androgyny*.

In addition, respondents asked to describe themselves use a different inferential context, which may alter the sense of a given term from that afforded by its original context. For example, when thinking of the ideal housewife/mother, loyalty (an item on the BSRI femininity scale) would seem to be a salient feature of the mother's feelings about her family. On the other hand, a football jock may think of loyalty in the sense of loyalty to his buddies, or to his team and to his school. This concept of loyalty is hardly indicative of femininity or of emulation of a female sex stereotype.

It could be argued that all personality inventories feature indeterminant inferential contexts, and so singling out the BSRI and the PAQ is unfair. But the problem is not so much one of general ambiguity, but rather one of biases in self-report, or automatic adjustments to one's sex, systematically related to the notion of what is measured. The sorts

of referential vagaries noted above contribute to a surface impression of equivalence not necessarily supported by the underlying evidence. Indeed, sex differences in the results of Bem's (1976) experimental studies lend credence to this premise, that responses differ in their significance by sex.

Fundamentally, the appropriateness of a traditional individual-differences approach to this general domain is questionable. There are special characteristics of masculinity, femininity, sexual identity, and sex differentiation, such as it is, in personality or behavior, that do not hold for any other individual-difference construct (with the possible exception of intelligence). For one thing, sex, the anchor for concepts of masculinity and femininity, is a universal attribute of the organism. The lay person and, until recently, the psychologist tend to assume the bipolar nature of masculinity and femininity because biological sex is thought to be causally implicated in trait differentiation. Masculinity and femininity are conceptually related to biological sex. They are also, at least in their ordinary sense, conceptually related to sexuality and sexual relations, universal phenomena of extraordinary salience and consequence. Finally, their relation to biological sex suggests another consideration. Sex is a major criterion for the structural differentiation of experience over the life cycle, given an extensively sex-segregated society. The implications of these considerations for the viability of psychological androgyny research and theory are explored in the following section.

Masculinity, Femininity, and Adaptation

Masculinity/femininity research and theory had always been characterized by an emphasis on the contribution of the construct to overall adaptation or adjustment. As a personality construct, masculinity/femininity was postulated to account for individual variation in indicators of adaptation or adjustment. The construct was assumed to be valid if it discriminated criterion groups that could be distinguished on the basis of a "relevant" adjustment indicator. Homosexuality in men, adjudged to be pathological and maladaptive, was one diagnostic criterion advocated by Terman and Miles (1936), and a notable amount of research was conducted investigating the predictive validity of various masculinity/femininity scales regarding male sexual object choice (e.g., Burton, 1947; Krippner, 1964; Manosevitz, 1970). In a similar vein, research was conducted to determine the contribution of masculinity/femininity to global adjustment (e.g., Mussen, 1961), schizophrenia (e.g., Reed, 1956), anxiety (e.g., Consentino & Heilbrun, 1964; Gotts & Phillips, 1968; Gray, 1957), obesity (e.g., Lefley, 1971), and alcoholism (e.g., Jensen & Hoffman, 1973), among other adjustment indicators. The persistent assumption was that masculinity in males and femininity in females is functional for adaptation. The assumption was never substantiated, though the limitations of the masculinity/femininity scales make it difficult to know whether these findings are attributable to construct validity problems or if they constitute valid disconfirmations of the hypothesis.

Psychological androgyny research has inherited the focus on adaptation from the masculinity/femininity research. However, the direction of the argument has been reversed: Androgyny (rather than exclusive masculinity or exclusive femininity) is postulated to facilitate adaptation or adjustment. Bem (1974, 1976, Note 1) has always nested androgyny in a broader notion of the basis of mental health, and her experimental studies are designed to demonstrate that androgynous subjects are more able to cope with the requisites of situations than are masculine or feminine subjects. Indeed, she describes her sex-typed subjects as having "behavioral deficits," arguing that they don't have the abilities necessary for effective action in certain types of situations. Similarly, Spence et al. (1975) demonstrated that psychologically androgynous subjects have higher self-esteem than do masculine, feminine, or undifferentiated subjects. They explain this finding as indicative of androgynous subjects' greater personal and social effectiveness.

Two major problems, however, stem from the focus of this research on the prediction of indicators of adaptation or adjustment. The first involves a persistent blurring between no-

tions of predictive validity and of construct validity. The second and more serious problem involves contradictions between psychological and sociological levels of analysis.

Predictive validity is equivalent to the "truth value", or "power" of a theory, which increases as the hypotheses deduced from the theory are confirmed (Wiggins, 1973); it is not synonymous with construct validity. Construct validity is a feature of a particular measure of a personality construct and is established by a complex set of procedures determining the plausibility that the measure measures what it purports to measure (Campbell & Fiske, 1959; Cronbach & Meehl, 1955; Nunnally, 1967; Wiggins, 1973). The construct validity of a measure cannot be established by demonstrating its predictive validity. Yet the psychological androgyny researchers have attempted to do precisely that. They have reasoned that if androgynous subjects are more flexible in handling diverse situations or evidence more positive self-regard compared to the other categories of subjects, this must be due to differences in the sex type between the four categories of subjects. The notion of the function of sex type for adaptability or adjustment is so entrenched that the construct validity of the BSRI and the PAQ is taken for granted. Oddly, there are numerous behaviors that are popularly recognized to covary with masculinity and femininity, but neither the masculinity/femininity researchers nor the psychological androgyny researchers have tried to determine their relation to the sex-type measures. Consider, for example, masculine males. They are generally assumed to "sow their wild oats," to put a high priority on physical attractiveness in the choice of a mate, to value male friendships, and to socialize frequently in male groups. In contrast, feminine females are generally assumed to invest considerable amounts of time in their physical appearance, to prefer the company of males over females, and to subordinate commitments to female friends to commitments to male friends. Feminine males are assumed to be given to stereotypically feminine gestures and to enjoy sitting about and gossiping. These examples are obviously suggested by popularly disseminated caricatures. Readers may think of still other behaviors that are widely believed to be indicative of masculinity and femininity. What is important for establishing the construct validity of the BSRI and the PAQ is their discrimination of behaviors that reflect dispositional sex-differentiated preferences on the part of the actor, rather than behaviors that reflect such relatively non-sex-related attributes as self-esteem, self-confidence, intelligence, or conservatism.

The confusion between construct validity and predictive validity characteristic of psychological androgyny research and theory can easily be rectified by further research. A more serious problem of contradictions between psychological and sociological levels of analysis is created by the focus on adaptation or adjustment as criterion variables for sex-identity research. Given the overall argument of psychological research and theory, the use of criterion indicators of adaptability or adjustment ignores the fact that many situations continue to be structured with respect to sex, such that sex-appropriate behaviors generally procure psychological and material rewards, whereas sex-inappropriate behaviors may be costly. If situational appropriateness is to be a criterion of adjustment, it would be "maladjusted" to behave in a sex-inappropriate manner. And, given that behavior is at least partially a function of situations (e.g., Mischel, 1968), men and women will act differently because they have different ongoing tasks, responsibilities, and access to resources. The existence of sex segregation and discrimination in the paid labor force has been amply documented, revealing differential sex-dependent contingencies surrounding entry into occupations, considerable sex segregation in occupational distribution, and striking sex differences in earnings (Blau & Jusenius, 1976; Kanter, 1977; Tangri, 1972). Also, in spite of the increasing participation of married women in the work force, time-budget studies show that sex-based division of labor in the family has persisted (Robinson, 1978; Walker & Woods, 1976). Within the coeducational college environment, which is the setting for practically all of the psychological androgyny research, and which is, perhaps, the least sex-segregated

setting of any institutionalized environment, one still discerns ample evidence for differential constraints: in athletic programs, in student political organizations, and in extracurricular activities (Douvan, 1975).

At a level that is more immediately experienced by the average college student, norms governing appropriate behavior in interpersonal relationships in informal as well as formal settings still differ depending on the actor's sex. People are relatively aware of these norms. Their impact on behavior is suggested by the rather distressing findings of a study (Zanna & Pack, 1975) that found that when a potential male partner was described with desirable characteristics, female subjects' self-descriptions were influenced by information about his ideal woman: They tended to describe themselves in conventional terms when the partner's ideal was conventional and in unconventional terms when the partner's ideal was unconventional. When the partner was undesirable, information about his ideal had little impact on the subjects' self-descriptions. The women students clearly geared their behavior to reward contingencies present in the situation.

Snyder and Skrypnek provide further evidence (described in Snyder, Note 4) of the behavioral impact of sex-contingent expectations. They located two individuals in separate rooms and required the pair to divide a series of tasks varying in their sex specificity. Since the dyads could communicate only by means of a signaling system, neither member could detect the sex of the other. In one condition, the "perceiver" was told that the "target" was female; in a second condition, the perceiver was told that the target was male. Snyder and Skrypnek found not only that the perceived sex of the target influenced the outcome of the division of labor process, but also that the targets themselves began to initiate choices consistent with their assigned sex.

Once we consider that situations involve different contingencies and behavioral norms for males and for females, the use of adaptability or adjustment in androgyny research becomes contradictory. Bem's experimental studies demonstrate that androgynous subjects are capable of sex-inappropriate behavior when the demand characteristics of the experiment clearly tell the subjects that sex-inappropriate behavior is situationally appropriate. The studies do not demonstrate that androgynous subjects engage in sex-inappropriate behavior when sex-appropriate behavior is situationally appropriate or rewarding. And if androgynous subjects are to be distinguished by their ability to adapt to situational requisites, will they not act in sex-role-congruent ways when such acts enable them to obtain psychological, interpersonal, and material rewards? The fact that androgynous subjects endorse both masculine and feminine traits in no way militates against this point. Consider the female college student who is analytical, assertive, competitive, independent, individualistic, and self-reliant in her studies, as all good students are expected to be, and affectionate, childlike, flatterable, loyal, soft-spoken, sympathetic, understanding, warm, and yielding with her boyfriend, as all good girlfriends are expected to be. She would be classified as androgynous by Bem, yet her behavior is not independent of sex role norms.

Even though many of the traits may be statistically orthogonal and although individuals, for example, may be both dominant and submissive between situations, within situations their behavior may still be constrained by interaction rules that affect the sexes differently. Bem argues that androgynous individuals are better off than masculine or feminine individuals because they are capable of being, to take one example, yielding in situations in which it is appropriate to yield and, to take another example, assertive in situations in which it is appropriate to be assertive. This argument neglects the fact that norms and rules governing behavior in settings are often sex specific and are contingent on the sex composition of the actors in the setting (cf. Ruble & Higgins, 1976). For example, in a given social interaction it may be appropriate for a woman to yield to a man, but highly inappropriate for a man to yield to a woman. In other settings, the woman may be assertive, but such behavior may not procure or maintain authority as the man's behavior does in interaction with the woman.

Because many situations are structured with

respect to sex in such a way that sex-inappropriate behavior is costly, we should expect to find sex differences in the frequencies of certain types of behavior, which, in turn, have implications for how one might realistically describe oneself as an actor in general. Bem's (1974) data does provide some evidence for this line of reasoning, though she has never considered the implications of the following findings. She found significant sex differences in androgyny scores, with females scoring on the feminine side of the scale and males scoring on the masculine side. In addition, only 6% of the males at Stanford and 9% at Foothill were feminine, and only 8% of the females at Stanford and 8% at Foothill were masculine. These findings suggest that there are definite constraints either influencing respondents' willingness to endorse cross-sex-associated items exclusively or influencing respondents' frequency of acting in ways that could be described with cross-sex-associated items. Either explanation would be consistent with the notions that situations are structured with respect to sex at both institutionalized and informal social levels, and that differential contingencies influence the behavior of males and females, their dispositions to behave in varying ways, and consequently their perceptions of self as an actor in general.

Spence and Helmreich (1979) argue that the influence of sex-contingent norms of behavior "cannot be used as a criticism of personality instruments such as the PAQ; it merely serves as a warning that one should not make predictions about behavior as a function of PAQ scores without taking situational variables into account" (pp. 1037–1038). Elsewhere they stipulate that "expression of the personality traits tapped by the PAQ is likely to be exaggerated when these response dispositions are congruent with situational demands . . . and likely to be suppressed or modified when they are incongruent" (p. 1037). For support of this point they cite a study by Megargee (1969), who fully crossed sex and high- and low-dominant subjects in dyads and asked each pair to choose a leader for working on one of two laboratory tasks. In by far the majority of mixed-sex pairs, the male wound up as the leader, regardless of either partner's dominance rating. Dominant women were more likely to participate verbally in the choice of a leader but were not more likely to be a leader than nondominant women were, whether paired with a high- or a low-dominant male. Spence and Helmreich neglect to point out that this effect occurred regardless of whether the task was of a "masculine" sort, involving industrial mechanical work, or of a "feminine" sort, involving clerical work and verbal talent.

Clearly situational demands and press can inhibit the expression of a personality trait. However, the investigator ought to be able to specify, in a theoretically plausible fashion, those situations in which the personality trait should predict behavior and those situations in which the trait should not predict behavior. Congruence with situational demands is not a valid criterion, at least unless the contribution of situational demands can be distinguished from the contribution of the personality disposition. After all, there is no a priori reason to assume that situational demands always overshadow the influence of personality dispositions. The Megargee study is a case in point. It is not clear to us that one would have predicted no effect of the sex-typing of the task on the expression of the personality trait *dominance* on the part of the women subjects. Furthermore, if situational contingencies and social expectations repeatedly overwhelm the influence of assumed dispositions on behavior, one can hardly expect the targets of these powerful forces to sustain dispositions or self-perceptions largely independent of their behavior.[2]

---

[2] Interestingly, most of Bem's experimental studies involve behaviors directly tapping the behavioral content of the items on the BSRI masculinity and femininity scales. Spence (Note 5) cautions against assuming that either the PAQ or the BSRI masculinity and femininity scales relate to other sex-related aspects of behavior or personality. No one has found any association, for example, between psychological androgyny and attitudes towards women's rights (Jones et al., 1978; Spence, Note 5). Spence and Helmreich observe that in general "the psychological dimensions of masculinity and femininity . . . are only weakly related within each sex to the broad spectrum of sex-role behaviors" (1978, p. 3). They argue that this state of affairs is legitimate and even

Underlying the notion of psychological androgyny is the assumption that sex typing per se is dysfunctional or maladaptive, and that men are as disadvantaged as women, since they are expected to conform or aspire to a stereotypic ideal of masculinity, just as women are expected to conform to a stereotypic ideal of femininity.

Neither data produced by Bem and by Spence and Helmreich nor observations of the relative well-being of men and women in our society support the conclusion that individuals evidencing exclusively masculine traits are in fact as disadvantaged as those evidencing exclusively feminine characteristics. Bem's findings show that feminine females are the least capable of the lot and that little difference obtains between masculine and androgynous females. Spence and Helmreich's subjects scoring high-feminine/low-masculine display considerably lower self-esteem than those scoring high-masculine/low-feminine.

Most of the masculinity traits included in the BSRI and the PAQ reflect skills that enable individuals to access resources and control situations and social interactions. Although masculine individuals may forfeit some emotional gratifications, they have survival skills. On the other hand, most of the femininity traits do not reflect skills: Compare child-like, shy, guillible, soft-spoken, to analytical, assertive, independent, self-reliant, items on the BSRI femininity and masculinity scales, respectively.

Jones, Chernovetz, and Hansson (1978) conducted a series of studies designed to investigate Bem's (Note 1) hypothesis that psychologically androgynous individuals are more adjusted than sex-typed persons, in consequence of their greater behavioral flexibility or more extended behavioral repertoire. They used a variety of dependent measures, including self-esteem, locus of control, problems with alcohol, helplessness, sexual maturity, and neurosis, as adjustment indices, as well as a series of attitudinal variables. They found that masculinity rather than androgyny generally predicted greater adjustment and flexibility, for both sexes. They also found that both male and female feminine and androgynous subjects expressed a desire to become more masculine. These results do not vindicate neglect of the fact that behavior occurs in situations all too often governed by asymmetrically sex-differentiated norms and contingencies. More important, these observations suggest that the term *psychological androgyny* may be utterly arbitrary, inasmuch as persons classified as androgynous are no less aware or concerned about the social implications of their sex and its ramifications for their behavior than are sex-typed persons.

Indeed, how could they be? It is impossible to escape the social consequences of one's sex. Sex is an immediately perceptible feature of every person. Regardless of one's own inclinations, one's sex evokes and elicits sex stereotypes in others. Thus one is repeatedly assaulted by the influence of sex-contingent expectations and norms. Furthermore, as the studies by Megargee (1969), Ruble and Higgins (1976), Snyder and Skrypnek (Snyder, Note 4), and Zanna and Pack (1975) suggest, individuals are easily swayed by sex-contingent expectations, quickly adopting these norms as their own. Both the influence of one's sex on others' perceptions and expectations on oneself and one's actions are unavoidable. The negotiation of social experience involves participating in systems of behavioral rules that mark the sex of each and

---

to be expected, given that the strength of some sex role norms can create homogeneity in behavior regardless of personal inclination, (1978, cf. p. 28). This caveat creates certain difficulties. On the face of it, at least, it is unsatisfactory to show that the BSRI and the PAQ scales simply tap the traits they contain. If they are only trait lists, why are they labeled Masculinity and Femininity scales? It is insufficient to derive their sense purely from aggregate distinctions. That would be equivalent to developing and labeling a scale "Whiteness" because it comprises intelligence items that discriminate the races on the average, and using the scale to categorize individuals as white, nonwhite, and beyond coloration, regardless of their race. The labels and the research that has been conducted with these scales clearly suggest the assumptions that there is something about individual personalities that is being measured, and that that something is sex related. Furthermore, there are situations so weakly governed by sex-role norms that personality dispositions ought to predict whether the person's behavior is sex role conforming or deviant. These situations ought to be specifiable in advance.

every actor. Considering the role of sex in the very architecture of experience and behavior, the notion of psychological androgyny, with its implication of freedom from sex-related social effects on personality and behavior, is arbitrary at best.

The present article has raised a number of questions about the explicit and implicit claims of psychological androgyny research and theory. We have addressed issues concerning the interpretation of respondents' scores on the BSRI and the PAQ, assumptions about the definitions of masculinity and femininity, and the general focus on adjustment and mental health as criterion variables. Throughout our questioning of psychological androgyny research and theory, we have repeatedly emphasized that sex is a structural feature of situations and of ongoing organizations of life experience, in that settings and ongoing organizations are characterized by sex-differentiated behavioral norms, cost/reward contingencies, and access to resources. In general a psychological theory of sex identity or sex differences should recognize this fact, because individuals apprehend the significance of their sex at least partly as a function of their experience with sex-differentiating social and institutional environments.

The diversity and complexity of the social and sociological functions of sex do not automatically exile the factor from the province of psychology, though. Psychological androgyny research introduced the role of cognitive and motivational processes in sex differentiation of behavior, if only by deriving masculinity and femininity scales from general sex stereotypes. A potentially more fruitful approach to the measurement of cognitive structures linking sex, other person features, and behavior rules would begin with concepts of more immediate relevance for self-perception and self-direction than global sex stereotypes and would take advantage of recent developments in cognitive psychology regarding formal and structural features of cognitive organizations (e.g., Abelson, 1976; Cantor & Mischel, 1977; Minsky, 1975; Mischel, 1977; Neisser, 1976; Rosch, 1975). One possible conceptual form suggested earlier is the person prototype. Psychological androgyny researchers define masculinity and femininity in personality-trait terms, as clusters of attributes fixed across time and across situations. Possibly a more adequate representation of person factors that tend to sex-differentiate behavior would focus on the cognitive mediation of a sense of self by concepts connecting sex, other attributes, and their general valence and would examine the effects of those concepts on behavior. As noted earlier, Wittgenstein's (1958) notion of a family of concepts, with varying overlap or criteria of resemblance, is probably preferable to the notion of a general sex stereotype, for purposes of investigating individually initiated, sex-differentiated behavior. In any case, it is important to recognize that existing measures of sex stereotypes carry implicit assumptions about the nature of cognitive representations of world knowledge involving gender. Those assumptions require explicit examination.

Finally, the profound and extensive distinction by sex still characteristic of our society is precisely what has been brought to our attention by the feminist movement. Individuals are willy-nilly caught in the process of contending with social as well as biological implications of their sex that have serious ramifications for their self-regard and for major and minor life decisions. From this perspective, there is no such thing as psychological androgyny. Individuals living within a culture in which sex is deeply structurally embedded are inevitably subject to a complex nexus of social relations that locate them in social space partly as a function of their sex. Rather than constructing personality typologies in which some types of people are accorded privileges over others, even so bland a privilege as the mental health of conformity to situational requisites, it would be far more beneficial for psychologists to investigate the means by which people in general participate in social processes that persistently rely on sex for differential allocation of resources, bases of power, social authority, and prestige.

The Many Faces of Androgyny: A Reply to Locksley and Colten

Janet T. Spence and Robert L. Helmreich
University of Texas at Austin

In their methodological and theoretical critique of the Bem Sex Role Inventory (BSRI) and the Personal Attributes Questionnaire (PAQ), Locksley and Colten assume that there is a singular androgyny theory to which the rationale and the psychometric properties of these instruments are inexorably tied and that each is intended to be a broad-gauged measure of masculinity and femininity or of global self-images of these concepts. The present authors, however, conceive of the PAQ as a specialized measure of socially desirable instrumental and expressive characteristics, objectively defined trait dimensions that distinguish between the sexes to some degree and thus may be labeled "masculine" and "feminine." Further, they hypothesize that these dimensions have complex and frequently weak relationships with other components of masculinity and femininity, although simultaneously having implications for significant areas of functioning. When the PAQ is viewed from this theoretical perspective, the authors suggest that Locksley and Colten's criticisms directed at its rationale, its empirical properties, and its definition of androgyny become largely inappropriate or irrelevant.

In their article "Psychological Androgyny: A Case of Mistaken Identity?", Locksley and Colten (1979) vigorously criticize the theory of psychological androgyny as well as both the rationale and the methodology of the major instruments used to measure androgyny—the Bem Sex Role Inventory (BSRI; Bem, 1974) and the Personal Attributes Questionnaire (PAQ; Spence & Helmreich, 1978; Spence, Helmreich, & Stapp, 1974, 1975). We find ourselves in agreement with a number of their specific points. However, our overall assessment of the research done with the PAQ in particular leads us to different conclusions, in large part because we view our instrument and its relevance to androgyny theory, and to such broad concepts as masculinity and femininity and sex role identity, from a perspective that differs from that of Locksley and Colten and that of many other androgyny researchers. Within the context of our theoretical perspective, we will discuss some of Locksley and Colten's major arguments, in an effort to clarify further conceptual and methodological issues.

What has come to be known as androgyny theory rests essentially on the proposition that the perpetuation of traditional sex role distinctions is dysfunctional; a society in which differences between the sexes were reduced to the minimum dictated by anatomy would be not only more just but also healthier for its members. A companion proposition, articulated most clearly by Bem (1974), is that masculinity and femininity, so long regarded as terms representing two ends of a single bipolar dimension, the independent dimensions. Both masculine and feminine characteristics may coexist in the same individual, with those individuals exhibiting a relatively high degree of both being labeled "androgy-

Preparation of the manuscript was partially supported by National Science Foundation Grant BNS 76–17376 (Janet T. Spence and Robert L. Helmreich, principal investigators).

nous." [1] In this theoretical context, masculinity and femininity are global, unidimensional concepts, referring to constellations of covarying attributes and behaviors that normatively distinguish between men and women, and/or to individuals' conceptions of their own masculinity and femininity.

Locksley and Colten (1979) express reservations about accepting the assumption that individuals high in both masculinity and femininity (in these global senses) are better adjusted than sex-typed individuals are, in both a psychological and a sociological sense. Other major criticisms concern the usefulness of these global notions of masculinity and femininity, and the conceptual and methodological deficiencies of the BSRI and PAQ in measuring these constructs. It is to these latter issues that we shall largely address ourselves, confining our discussion to the PAQ, since both its theoretical rationale and its psychometric properties are not identical to those of other androgyny measures.

Although acknowledging at several places that our views and Bem's (e.g., 1975, 1977) are not identical, a pervasive theme underlying Locksley and Colten's critique is that there is a single androgyny theory to which the construction and content of the BSRI and the PAQ, as well as the research done with these instruments, is firmly tied. They also imply that the PAQ, as well as the BSRI, is—or is intended to be—a measure of such general notions as sex identity, sex stereotypes, or sex differences in personality. However, our conception of what the PAQ measures is quite narrow, and both our definition of androgyny and the theoretical suppositions in which our research with the PAQ has been embedded depart in several critical respects from androgyny theory as just described. It is not so much that we disagree with the tenets of that theory as the fact that we are not talking about quite the same things.

To respond to the criticisms offered by Locksley and Colten (1979), it is crucial to present first the theoretical and empirical rationale underlying the development of the PAQ. The 24-item version of the PAQ, used in all of our research following our initial investigation (Spence et al., 1974, 1975), consists of certain clusters of socially desirable socioemotional trait descriptions reflecting what are typically labeled *personality* characteristics, to distinguish them from such other psychological attributes as cognitive abilities or styles, values, attitudes, and so forth. The instructions are general, making no reference to gender, and nothing in the content of the items makes the intent of the instrument obvious. Indeed, the items are ones that appear in identical or similar form on other conventional personality inventories, whose developers and users have, at most, only incidental interest in sex differences.

The development of the PAQ was guided simultaneously by theoretical and empirical considerations. The initial (55-item) version of the scale was drawn from a larger pool of items for which ratings of the typical man and the typical woman (personality stereotypes) and the ideal man and the ideal woman had been obtained. The 55 items chosen for the PAQ were selected from those judged by both sexes to distinguish between the typical man and the typical woman (both adults and individuals of college age).

In using stereotype data to select items for the PAQ, we were in part expressing our conviction that traits about which there was consistent agreement would be a good source of items that would yield actual differences between the sexes and thus permit us to devise an instrument with which we could test a number of hypotheses, such as a dualistic versus a bipolar conception of masculine and feminine *personality traits*. The usefulness of this method of selection is demonstrated by the fact that sex differences in self-reports appeared in the expected direction on every item.

Items were assigned to subscales on the

---

[1] Bem's (1974) androgyny measure, the BSRI, was initially scored by finding the difference between scores on masculinity and femininity scales, and androgyny was defined as a relative balance between the two scores, regardless of their absolute level. We, along with others, have argued that, to correspond more closely to accepted usage, the term should be reserved for those relatively high in both dimensions, a usage that Bem (1977) now accepts and that was also adopted by Locksley and Colten.

basis of these stereotype ratings as well as ratings of the ideal man and the ideal woman. Traits that were stereotypically more characteristic of males but socially desirable to some degree in both sexes were assigned to a Masculinity (M) scale, while traits that were more stereotypically characteristic of females but socially desirable in both sexes were assigned to a Femininity (F) scale. This method of assignment resulted in two groups of items whose content by and large confirmed the speculations of a number of theorists, as well as popular thought, about the fundamental differences between the personalities of men and women. These differences have been characterized by Bakan (1966) as a distinction between masculine *agency* (a sense of self-assertion and self-protectiveness) and feminine *communion* (a sense of selflessness and need to identify with others) and by Parsons and Bales (1955) as a distinction between instrumental and expressive traits. Analyses of the data from several samples of college students indicated significant sex differences in M and F scale scores and also a slightly positive rather than strongly negative correlation between scales in each sex. The latter outcome refuted the implications of the bipolar M–F model of these personality attributes, suggesting instead the usefulness of a dualistic approach.

Use of the ideal ratings resulted in a third scale with more bipolar properties. This scale, labeled Masculine–Feminine (M–F), contains items for which ratings fell toward opposite poles for the ideal man and the ideal woman. The scale is mixed in content, containing items dealing with instrumental qualities, such as "aggressive" and "dominant," which are seen as somewhat desirable for men but not for women, and other items, such as "excitable in a major crisis" and "cries easily," which reflect emotional vulnerability and are seen as somewhat desirable in women but not in men.

Following our initial study, we shortened each scale to eight items, retaining those that showed the best psychometric properties and that also illustrated instrumental and expressive personality traits. (Thus, such items as "athletic" and "good at math and science" were dropped.) The current PAQ may therefore be described as a quite conventional personality test in the self-report mode, consisting of clusters of socially desirable instrumental (masculine) and expressive (feminine) traits. The ultimate justification for the appellations Masculinity and Femininity lies in the demonstration that the clusters of items discriminate between the sexes in their self-reports.

The decision to limit the content of the scales to personality traits describing instrumental and expressive qualities was a theoretical one. Space limitations preclude an explication of the considerations underlying this decision. They led us to conclude, however, that the essential core both of the socially sanctioned and expected differences in the personalities of men and women and of the actual differences between them, as indicated in self-reports, lay within the realm of instrumentality and expressiveness. Implied in this statement is our expectation that the instrumental–expressive conceptualization has considerable transcultural and transgenerational validity in distinguishing between the sexes.[2]

Purportedly biological sex differences in expressive and instrumental personality characteristics have frequently been used to explain traditional instrumental versus expressive role divisions along sexual lines, and acceptance of the functional value of these divisions has led to justifications for socialization practices that attempt to assure the development of a high degree of expressiveness in girls and of instrumentality in boys. Development of a personality scale narrowly confined to "mas-

---

[2] The PAQ does not contain all possible exemplars of instrumental and expressive traits. We do not anticipate that in any given group, actual or expected sex differences will necessarily be found for the entire universe of instrumental and expressive qualities or that exactly the same instrumental and expressive qualities will distinguish between men and women in all cultures and nationalities (see Spence & Helmreich, 1978, for a further discussion of these issues). However, in several completed and ongoing cross-national investigations with the PAQ, limited as it is in content, we have found more similarities than differences with comparable United States samples. As we will discuss shortly, our PAQ results with United States samples are quite consistent across a broad range of chronological ages and socioeconomic groups.

culine" instrumental characteristics and "feminine" expressive characteristics allows exploration of the validity of many suppositions about the relation between these personality dimensions and other types of gender-related phenomena. Our suspicions (which formal evidence is now verifying) were, on the one hand, that the relation between instrumental–expressive personality traits and other gender-related phenomena would turn out to be considerably weaker and/or more complex than had been presumed and, on the other hand, that these trait continua would have important implications for significant areas of functioning without regard to gender.

Independent investigation of the effects of PAQ-defined masculine instrumentality and feminine expressiveness on criterion variables could proceed because the M and F scales were found to be essentially orthogonal. Once the separate relations of M and of F to criterion measures are discovered, their simultaneous contribution to criterion variance becomes important to determine. We have found that the median split method of jointly classifying subjects on M and F scores is a useful conceptual scheme for representing the combined influence of these scales on many dependent variables.[3] For mnemonic purposes, the four resulting cells have been given verbal labels: *Androgynous* (above the median on both M and F), *Masculine* (above the median on M, below on F), *Feminine* (below on M, above on F), and *Undifferentiated* (below on both).

As should be obvious from this description, we introduced the term *androgyny* simply as a convenient label to identify individuals who score relatively high on both the M and the F scales of our particular instrument. Within this context, it is merely a label that corresponds to the definition of the term in standard dictionaries (e.g., "1. having the characteristics or nature of both male and female," *Webster's New Collegiate Dictionary,* 1974). Locksley and Colten's statement that with respect to its "ordinary sense . . . the term *psychological androgyny* clearly implies 'of indeterminate sex, or not sex related' " (1979, p. 1023) is based on an extraordinary sense with which we are not familiar. In any event, androgyny, as we have used the term, has no particular theoretical import, being intended to indicate nothing more than a relatively high degree of both instrumental and expressive personality traits, as defined by the PAQ. The relation between androgyny in this personality sense and other types of androgyny (e.g., interest in both "masculine" and "feminine" hobbies) must be determined empirically.

Locksley and Colten express concern that "most psychological androgyny research has been conducted on college students and even on high school students," and they suggest that "the variance in scores permitting the categorization of androgynous persons may indicate only the lack of press from the defini-

---

[3] Widespread confusion surrounds the use of this method. On the one hand, it has been accepted by some with uncritical enthusiasm as a kind of genuine typology, suitable for use on all occasions. However, the conceptual model that best represents the conjoint influence of M and F must be sought for each new type of data, not assumed a priori. The median-split method has proved to be broadly useful for this purpose, but there is no theoretical reason to anticipate that this will be universally true. On the other hand, the median-split method has come under attack primarily on the grounds of crudeness, loss of information, and inaccuracy of classification into types (e.g., Pedhazur & Tetenbaum, 1979). The frequently suggested solution to the problem is to apply more sophisticated techniques, such as multiple regression, to the data, a suggestion not further amplified. The median-split method is indeed crude and is not the method of choice if one is seeking to maximize predictive accuracy for individual subjects. Our intent, however, has been to provide a conceptual heuristic scheme that will reveal, in a simple and easily communicable form, the nature of the conjoint influence of M and F on the criterion variable. Assuming that the method is properly used; more complex analyses, including regression techniques, should provide no new conceptual information. One should seek other mathematical schemes, such as regression models, when the median-split method proves inadequate or when one is seeking to maximize variance accounted for by using the measures appropriately as continuous variables. In the case of such variables as our measure of self-esteem, the maximum R^2 is produced by an equation containing the partials of M and F and the interaction term ($M \times F$). However, without a priori predictions concerning the joint influence of M and F on criteria, the mechanical use of stepwise regression can lead to conceptually misleading outcomes. See Spence and Helmreich (in press) for an extended discussion of these issues.

tions and constraints of adult sex-segregated social roles" (1979, p. 1021). We have now collected data from more than 1,300 middle-aged adults (Spence & Helmreich, 1978, Note 1). The most striking finding revealed by these data is their parallelism to the data obtained from college students in absolute scores on means and in variance of the scales, in the strength of sex differences, and in the percentage classified into each of the four M–F categories we have defined—a parallelism that exists even when the middle-aged sample is classified using medians drawn from a college population. Significant sex differences have also been found in highly selective populations, for example, between male and female PhD-holding scientists (Beane, 1976), and between male and female athletes (Helmreich, Spence, & Vacalis, Note 2). Further, our data (Spence & Helmreich, 1978) from "even high school students," who were much more heterogeneous in social origins than the samples described above, suggest that the pattern of sex differences, scale correlations, and distributions among PAQ categories is quite impervious to social class. We have recently developed a child's version of the PAQ (Simms, Davis, Foushee, Holahan, Spence, & Helmreich, Note 3) and have found similar sex differences on each scale among 6- and 7-year-old children, as well as variability within each sex.

In criticizing the BSRI, Locksley and Colten (1979) cite factor-analytic studies (e.g., Gaudreau, 1977; Moreland, Gulanick, Montague, & Harren, 1978) that produced four factors, and they suggest that this further weakens the assumption of unidimensional constructs conforming to the original labels assigned to the inventory's scales. Similarly, factor-analytic and discriminant-function data obtained from the BSRI by Pedhazur and Tetenbaum (1979) led these investigators to question the BSRI and the concept of androgyny on both theoretical and methodological grounds. Although there is a fair amount of overlap between the PAQ and the BSRI, and a moderate correlation between parallel scales, there are enough differences between the two instruments to suggest that the type of results found with the BSRI would not necessarily be found with the PAQ. The items contained on the BSRI are not confined to expressive and instrumental traits, and the methods of item-to-scale assignment were somewhat different (resulting in three gender-related scales on the PAQ vs. two on the BSRI). Finally, Gilbert and Strahan (1978) and Pedhazur and Tetenbaum (1979) have provided data suggesting that several of the BSRI F items are judged to be socially *undesirable* for both sexes.[4]

We have undertaken additional psychometric investigations of the PAQ that suggest the unidimensionality of the M and F scales. These investigations included examination of the structure of the item-correlation matrices obtained from high school, college, and adult respondents of each sex along with factor analyses. Using the techniques recommended by Dziuban and Shirkey (1974), the correlation matrices comparing the M and F scales of the PAQ were classified as highly appropriate for factor analysis in each sex in each sample.[5]

Both maximum likelihood and principal factor analyses of the M and F items—computed separately for each sex and each sample—yielded similar results in each instance. Two large, oblique factors emerged, one reproducing the M scale, the other the F scale.[6]

---

[4] The significance of inclusion of such items is suggested by results obtained with our recent extension of the PAQ (EPAQ; Spence, Helmreich, & Holahan, in press) to include Masculinity and Femininity scales containing socially undesirable traits. Very low correlations were found between parallel Masculinity scales and Femininity scales.

[5] The Kaiser-Meyer-Olkin measure of sampling adequacy and Bartletts test of sphericity were computed, and the off-diagonal elements of the anti-image covariance matrix were inspected for the 16 items of the M and F scales and the full 24-item PAQ in six samples, 1,010 female and 757 male high school students, 670 female and 477 male college students, and 243 female and 208 male adults (average age, 36 years). The results for each measure are reported in Helmreich, Spence, and Wilhelm (Note 4).

[6] Comrey (1978) discusses methodological problems in factor-analytic studies. Many of these are evident in analyses of masculinity and femininity measures (see, for example, the discussion by Pedhazur and Tetenbaum, 1979) of the BSRI. Our analyses

Consistent with the correlations obtained with the unit-weighted M and F scales, the two factors had a low positive correlation (average $r = .08$ across the six samples).

Of greatest interest are the results obtained from adult respondents. Our sample consisted of 243 females and 208 males, all of whom were married and the parents of elementary school children. These respondents were clearly familiar with the definitions and constraints of adult, sex-segregated social roles. The fact that the same clusters of traits emerged in this sample provides reassuring evidence for the theoretically postulated trait dimensions. These data further suggest that the derivation of constituent masculine and feminine trait constellations from stereotypically perceived aggregate sex differences is, contrary to Locksley and Colten (1979), a reasonable and valid method of operationally defining these constructs. The soundness of the method is shown in the stability of sex differences across disparate groups as well as in the homogeneity of the trait clusters. (Indeed, the use of perceptions about aggregates to develop measures of individual differences represents a traditional approach to personality test construction.)

In sum, the PAQ is an instrument of restricted content, containing items describing personality traits of an expressive or instrumental nature. Our theoretical conception of such traits is that they are internally located response predispositions or capacities that have considerable transituational significance for behavior but are neither conceptually equivalent to behavior nor its sole determinant. Trait dispositions interact both with situational factors and with other properties of the individual to determine the form and the intensity of his or her responses in any given instance. As Fishbein and Ajzen (1974) have demonstrated, general trait measures are capable of a high degree of predictive accuracy if behavior is aggregated over multiple acts and types of situations. Adequate prediction of singular acts or of behavior in limited settings typically requires additional information.

Overt expression of the personality traits tapped by the PAQ is likely to be exaggerated when these response dispositions are congruent with situational demands (including role-related demands) and likely to be suppressed or modified when they are incongruent. An elegant example may be found in a study by Megargee (1969) in which high- and low-dominant individuals (as predetermined by a personality test) were paired and asked to choose a leader before beginning to work jointly on a laboratory task. In same-sex pairs and in mixed-sex pairs in which the male was high dominant (but *particularly* in the latter), the high-dominant member of the pair was chosen as the leader in the vast majority of instances. In mixed-sex pairs in which the female was high dominant, the low-dominant males ended up as the leaders about three quarters of the time. However, in most pairs, it was the dominant female who selected the leader, almost without exception designating the male. Thus, while the majority of these women conformed to implied sex role pressures, they actively utilized their disposition to dominate by manipulating the situation in a way that preserved the proprieties of male–female interaction. In this type of situation, dominant, assertive women, who neither valued conventional rules for the interactions between the sexes nor anticipated that role violation would result in negative consequences, would presumably have instead let nature (their own) take its course.

Other studies, some of them cited by Locksley and Colten, also demonstrate the effects of role demands on behavior. The fact that behavior is jointly determined both by situational variables and by relatively stable properties of the individual cannot be used as a

---

(Helmreich, Spence, & Wilhelm, Note 4) involved use of several techniques, construction of varying numbers of factors, rotations varying the obliqueness of the solution, and replications in independent samples. The convergence on a two-factor solution for the 16 items of the M and F scales thus seems methodologically justified.

Parallel factor analyses of the full 24-item instrument (including items assigned to the M–F scale) were also computed. These also yielded two main factors, with the F factor remaining unchanged and all of the M–F items loading on the M factor. The resultant M factor combines instrumentality with a lack of emotional vulnerability (i.e., feelings not easily hurt, never cries, etc.).

criticism of personality instruments such as the PAQ; it merely serves as a warning that one should not make predictions about behavior as a function of PAQ scores without taking situational variables into account.

Locksley and Colten take us to task for having neglected to point out (in an earlier version of our reply) that in the Megargee (1969) study, the "effect occurred regardless of whether the task was of a 'masculine' sort, involving industrial mechanical work, or of a 'feminine' sort, involving clerical work and verbal talent" (p. 1027). However, Megargee selected the clerical-verbal task as an example of a *sex-neutral* task, the label of "feminine" being supplied by Locksley and Colten. Our vote goes with Megargee. It remains an open question as to how feminine a task must be before men, as a group, are willing to relinquish leadership and women willing to assume it. Our reading of the attribution literature makes us suspect that when the task becomes one at which women are expected to be more competent than men, the leadership role will be shifted to women, with a concomitant downgrading of the importance of the task and the significance of being leader.

Locksley and Colten go on to comment that an "investigator ought to be able to specify, in a theoretically plausible fashion, those situations in which the personality trait should predict behavior and those situations in which the trait should not predict behavior. Congruence with situational demands is not a valid criterion, at least unless the contribution of situational demands can be distinguished from the contribution of the personality disposition. After all, there is no a priori reason to assume that situational demands always overshadow the influence of personality dispositions" (p. 1027). Apparently Locksley and Colten intend these remarks to be critical of our position, but we are hard put to determine what we are supposed to be disagreeing about. The importance of the Megargee study was in its demonstration that while certain forms of behavior were suppressed by high-dominant women, at the same time dominance behavior appeared in modified form. The study thus illustrated both the importance of situational factors, such as sex role demands, and that of trait dispositions such as measured by the PAQ. Criticizing the PAQ or our conceptions (or those of any investigator) because we cannot yet make detailed predictions about specific situational variables fails to recognize the very primitive state of knowledge in this field. Many of the theoretical presuppositions underlying decades of masculinity–femininity research have been found to be wanting. Those of us in this general area of research are attempting to develop a conceptual framework that will serve as a guide to more fruitful empirical research that will, in turn, allow the development of a more valid and sophisticated theoretical model.

One of the assumptions that has been rejected is that masculine and feminine behaviors or attributes are, of necessity, psychological opposites, two endpoints of a continuum. (We should note, however, that formal demonstration that masculine and feminine qualities are in fact essentially independent has been conducted only for *personality* instruments of limited content, such as the PAQ or the BSRI). A presupposition continuing to dominate this area of research is that gender-related phenomena, whatever their nature or level of operation, tend to covary: preferences or adoptions of the many categories of role-related behavior, sex differences in non-role-related attributes, sexual predilections, and the like. This assumption has led to the use of such broad concepts as sex role identity or masculinity and femininity, without any systematic attempt to decompose them. It has also resulted in attempts to measure these constructs by instruments of omnibus content, surveying a diverse array of gender-related phenomena, or by specialized instruments such as the PAQ or the BSRI with limited content domains. We have been critical both of these broad concepts and of the methods used to measure them. Omnibus measures, as we have noted elsewhere, would be perfectly satisfactory if, as is frequently assumed in both lay and scientific circles, various classes of masculine and feminine attributes and behaviors were highly correlated. Similarly, if such correlations could be demonstrated, it would be legitimate to generalize from a measure of a narrow subclass of mas-

culine and feminine attributes to other subclasses or to the class as a whole. However, a number of sources of evidence suggest that gender-related phenomena are only loosely associated, and that the relationships among various kinds of masculine and feminine behaviors tend to be weak or complexly determined. Thus, global constructs of masculinity and femininity or of sex role identification, based on an additive composite of the specific ways in which an individual resembles the typical member of his or her own sex, are likely to have little utility.

A profitable way to proceed, we have suggested, is to identify the principle components or classes of psychological phenomena related to gender and to devise methods to measure them so that their interrelationships may be determined. Part of our current research program is devoted to the development of additional measures which, like the PAQ or our Attitudes Toward Women Scale (AWS; Spence & Helmreich, 1972), tap a specific subset of sex-related phenomena, for example, overt behaviors in interactions with members of the opposite versus same sex, actual and preferred divisions of responsibilities in various areas within the homes of married couples, and so forth. Although the evidence supports our view that the intercorrelations among these measures and their interactions with situational variables are complex, it is premature to speculate on the exact nature of these complexities. The outcome of these investigations should suggest better articulated theoretical assumptions that should, in turn, suggest the directions in which future empirical research might fruitfully go. (It may turn out, of course, that gender-related phenomena are more tightly bound together than we suspect. This, however, must be demonstrated empirically, not taken for granted.)

Returning to the PAQ and the concept of androgyny, as defined by that instrument, our preceding discussion should make it obvious that we differ in several important respects from the position of Bem and her followers. First, we do not *define* the individual who is androgynous on the PAQ or BSRI (i.e., who has high scores on both the M and F scales) as a person who is "flexible" (i.e., who exhibits both masculine and feminine behaviors) across the general category of sex role behaviors. Nor do we *predict* that these androgynous individuals are likely to differ markedly from others in sex role behaviors that do not directly involve expressive or instrumental skills. Bem, in contrast, implies that the BSRI can be used as a measure of general sex role flexibility and hence assumes that androgynes, as defined by their high scores on the M and F scales, will not be sex-typed in role behaviors.

In her only experimental test of the sex role flexibility hypothesis, Bem (Bem & Lenney, 1976) preselected groups of individuals who, on the BSRI, were balanced ("androgynous," according to her initial definition), extremely sex-typed, or extremely cross-typed. In the experimental setting, subjects indicated their preference for, and comfort in, performing sex-appropriate versus sex-inappropriate tasks such as ironing a napkin or pounding a nail. Sex-typed individuals showed somewhat more avoidance of sex-inappropriate tasks than did the other groups, thus providing some support for the flexibility hypothesis. In a recently completed conceptual replication of the Bem and Lenney study (Helmreich, Spence, & Holahan, in press) using unselected subjects, we have found only minimal correlations between M and F scores on the PAQ and preferences for stereotypically masculine and feminine tasks, and no particular elevation of this type of role flexibility among Androgynous (high M and F) individuals of either sex. (Stronger relations, however, were found with a sex role attitudes measure.)

These findings lend credence to our suspicion that the personality traits measured by the M and F scales of the PAQ and the BSRI are only minimally related to many sex role behaviors that do not quite directly require instrumental or expressive skills. Thus we are extremely hesitant to generalize the findings obtained with these scales to other gender-related phenomena. It should not be assumed without empirical demonstration, for example, that masculine and feminine attributes in domains other than socially desirable instrumental and expressive personality traits form independent, orthogonal dimensions. Nor can

our data on the positive relation between self-esteem and the PAQ M and F scales (Spence & Helmreich, 1978; Spence et al., 1975) be used to conclude that individuals who are androgynous in a role sense are necessarily "healthier" or exhibit higher self-esteem than nonandrogynous individuals.

We indicated earlier that on theoretical grounds, we were impressed that the empirical process by which the PAQ scales were generated supported the conceptions of theorists such as Parsons and Bales (1955) concerning the distinction between masculine instrumental traits and feminine expressive traits. Locksley and Colten, however, express discomfort over this outcome. The instrumental–expressive distinction, they state, is not a good indication of the masculine–feminine dichotomy because "traditionally female activities, such as mothering, require instrumental behavior in order to be carried out effectively" (1979, p. 1021). Once more we see the invidious effects, endemic in the sex role literature, of the failure to distinguish between personality traits and sex role behaviors and responsibilities. Ironically, Talcott Parsons, who originated the proposal that the division in role responsibilities between the sexes could be characterized by the terms *instrumental* and *expressive,* and who also postulated that effective role performance demanded instrumental or expressive qualities of personality, *did not confuse the conceptual distinction between traits and roles.* However, we concur with Locksley and Colten, and, indeed, have said elsewhere (e.g., Spence & Helmreich, 1978), that it is fallacious to assume that the execution of expressive, feminine *roles* requires exclusively expressive personality traits; similarly, implementation of instrumental, masculine roles can benefit from expressive personality characteristics (e.g., management roles involving interpersonal relations). But as long as the difference in the two uses of *instrumental* and *expressive* is understood, each may legitimately be used to describe the differences between masculine versus feminine *roles,* and between masculine versus feminine *personality traits.*

We also reject the notion that, on the level of personality, a high degree of instrumentality is necessarily required for the effective performance of all stereotypically masculine tasks or a high degree of expressiveness for the performance of all stereotypically feminine tasks. Nonetheless, task analyses suggest that there is some degree of conjunction and that Parsonian theory, while perhaps overdrawn, is not without foundation. For example, some female-dominated professions, such as elementary education and social work, place a special premium on expressive or communal capacities and motives. There is also evidence (Wertheim, Widom, & Wortzel, 1978) to suggest that individuals of both sexes who are attracted to such professions score higher on the PAQ F scale than do their same-sex peers entering male-dominated professions. The latter, in turn, score higher on the M (instrumental) scale. Similarly, we have found that academic scientists, particularly female scientists, are higher in M (but no different in F) than unselected samples of men and women.

Data such as these suggest that instrumental and expressive characteristics have important implications for functioning in a number of significant areas. They further suggest that many activities that are normatively masculine (i.e., male dominated) demand instrumental attributes for their execution (whether or not they also benefit from expressivity) and that many activities that are normatively feminine (female dominated) demand expressive talents (whether or not they also demand instrumental qualities). Evidence also shows that differential socialization practices employed with boys and with girls actively encourage the development of instrumental attributes in the boys and expressive attributes in the girls (e.g., Block, 1973), in the at least partially correct belief that these personal qualities will be required for the discharge of traditional sex roles. The wisdom and justice of perpetuating sex role distinctions aside, there is failure to recognize that functioning may be enhanced by both types of qualities. Even worse, children—boys in particular—may be actively discouraged from developing and manifesting cross-sex characteristics, in the mistaken belief that instrumentality and expressivity preclude one an-

other (Foushee, Helmreich, & Spence, 1979).

Locksley and Colten (1979), however, denigrate the value of identifying the instrumental–expressive personality distinction as one component of masculinity–femininity by attacking the use of stereotype data to derive the PAQ and BSRI scales. A variety of arguments is advanced to buttress this position, several of them following from the assumption that the intent of these instruments was to measure global self-concepts of masculinity and femininity and/or concepts of masculinity and femininity in prototypic males and females. We will not respond to this set of arguments because, as we have indicated, our theoretical conception of the PAQ is that it is a more specialized instrument.

Other criticisms, however, are germane. They dispute the notion of a general stereotype, even on the specialized level of personality-trait attributions, citing as evidence a study by Clifton, McGrath, and Wick (1976). These investigators provided respondents with a list of adjectives, asking them to check those items that characterized the typical housewife, bunny, club woman, career woman, and woman athlete. Little commonality was found across roles in adjective choices. These results, while interesting for the light they shed on specific stereotypes, are quite to be expected. To use another example, one would not be surprised to find that, if asked to characterize men who are professional football players, people would agree that they are taller, stronger, and have fewer front teeth than nonathletically inclined males of the same age (all stereotypes that objective evidence would doubtless show are valid). This demonstration would not destroy the importance of the known difference between men and women in height and muscular strength, nor would it tell us much about people's beliefs (or the objective facts) about the number of missing front teeth in the typical member of each sex. We would also expect that female football players would be judged to be bigger and stronger than women in general—but not as big or strong as men. The existence of within-groups stereotypes does not demonstrate the nonexistence of between-groups stereotypes.

Locksley and Colten (1979), however, appear to argue from the Clifton et al. (1976) data that general stereotypes about the personality traits of the typical or the ideal man and of the typical or the ideal woman do not exist, or that, if they do exist, they are to be found only among high school and college students and others who have not experienced adult role constraints and conceptions, and/or that they represent stereotypes about the prototypic "housewife/mother and career man." In developing the PAQ, we obtained two types of stereotypic ratings (from independent samples), one for the typical male and the female adult and the other for the typical male and the female college student (who has not yet married or launched upon a career). Only those items for which significant stereotyping occurred under both sets of rating instructions were chosen for our questionnaire. Further, inspection of stereotype data obtained from older samples (e.g., Broverman, Vogel, Broverman, Clarkson, & Rosenkrantz, 1972; Rosenkrantz, Vogel, Bee, Broverman, & Broverman, 1968) does not confirm the contention that these stereotypes can be found only among younger inexperienced groups. Although cultural and subcultural differences in stereotypes about specific traits may well exist (Spence & Helmreich, 1978), what is most striking about the extant findings is the amount of agreement, over a wide age span of raters and rating targets, about the types of characteristics that distinguish the sexes. Finally, as we have noted, sex differences in self-reports on the PAQ M and F scales have also been found not merely in college students but also in diverse samples varying widely in age, ethnicity, and socioeconomic background.

Locksley and Colten claim further that "general sex stereotypes may be too global for interpreting and guiding behavior at the level of individual self-perception or self-direction" (1979, pp. 1021–1022). Two issues are involved here: the influence of sex stereotypes in guiding reactions toward others and in guiding reactions toward the self. With respect to the former, the danger of stereotypes

is not only that they tend to exaggerate both the number of temperamental characteristics that differentiate the sexes and the magnitude of these differences, but also that they too often result in crucial policy decisions discriminating against women and girls, based on the actual or supposed characteristics of females as a class versus males as a class. Women should be excluded from positions of authority because they are too emotional; girls should not be allowed to play Little League baseball because they are too fragile; women should not be admitted to graduate school because they are not highly motivated and are likely to drop out to get married and have babies; and so forth ad nauseum. Determination of the conditions under which information supplied about an individual man or woman will reduce the role of sex stereotypes in judgments about that individual is an important area of investigation. However, instances in which sex stereotypes have been the primary determinant in reaching decisions are too numerous and too serious to dismiss as trivial the influence of general stereotypes on people's lives.

The influence of sex stereotypes about masculine versus feminine personality characteristics in guiding self-behavior is a complex question. We should point out first that we as investigators, rather than the respondents, have labeled the PAQ scales "masculine" and "feminine," labels justified by the fact that sex differences in self-report are consistently found. The same appellation can be applied to other types of personal qualities and behavior that objectively differentiate the sexes, whether or not there is general awareness about the existence of particular types of sex differences and whether or not they are positively sanctioned. But, as we have written elsewhere:

> Masculinity and femininity can also be regarded as global aspects of the self-concepts that men and women directly identify in these or equivalent terms (such as being a "real man" or a "real woman").

We then went on to state:

> Individuals . . . have organized belief systems, however poorly articulated, about the psychosocial meaning of being "a man" or "a woman" and can be expected to have incorporated these beliefs into their sense of self. These belief systems, our observations suggest, are compounded of many elements: assumptions about appropriate sex-roles, characteristics of the self such as personality attributes and cognitive abilities, physique and physical appearance, styles of speech and body movement, sexual behavior, and so forth. One can expect that individuals belonging to the same culture or subculture will be reasonably similar in identifying the factors contributing to masculinity and femininity in themselves and others in the sense that they will be drawn from a common pool and will not be completely idiosyncratic. Individuals' definitions of masculinity and femininity, however, are likely to be based on complexly weighted sets of indicators that not only vary from one person to another but also change with age and may even differ when individuals are assessing themselves as opposed to others. (Spence & Helmreich, 1978, pp. 115–116)

How salient instrumental and expressive characteristics tend to be in the modal individual's self-concept of masculinity or femininity remains problematical. Hence the availability of these characteristics as models for more or less self-conscious guidance of behavior in situations in which gender per se is salient is unknown.

We have also suggested the importance of determining the nature of individuals' self-concepts of their own masculinity or femininity and their global conceptions of masculinity or femininity in others, as well as the importance of outlining some of the elements that might enter into these conceptions. Locksley and Colten have made the valuable proposal that techniques from cognitive psychology could fruitfully be employed to discover the structure of these global concepts. We regard such efforts as complementing—rather than supplanting—the study of masculinity and femininity, objectively defined from the perspective of the investigator. Whatever the place of instrumentality and expressivity in these global concepts, the fact remains that these personality dimensions have been shown to be significant determinants of behavior and that they do differentiate the sexes to some degree.

In the final section of their critique, Locksley and Colten observe that research and theory on masculinity and femininity have always emphasized the contribution of sex roles to adaptation or adjustment. In fact, they state, claims for the validity of the constructs

have often been based on their ability to discriminate between the adjustment levels of criterion groups. In contemporary theory, superior adjustment is claimed for androgynous individuals, whereas previously, superior adjustment was attributed to sex-typed men and women. The authors contend that this emphasis on adjustment by current androgyny theorists has led to two major problems. The first, they suggest, is a confusion between predictive validity and construct validity. (As they define the terms, predictive validity refers to a confirmation of the hypotheses derived from a theory, whereas construct validity refers to demonstrations that a measure taps what it purports to measure.) They also imply that efforts to establish the construct validity of the BSRI and the PAQ have been lacking, predictive validity having been mistaken for construct validity. The second problem, they state, reflects a confusion between psychological and sociological levels of analysis.

We agree that there has been confusion between construct and predictive validity, but our analysis differs from Locksley and Colten's. With the exception of her study with Lenney (Bem & Lenney, 1967), Bem's experimental studies have set up situations that were designed to elicit quite directly either instrumental or expressive behaviors. The results of these studies (Bem, 1977) generally showed that in situations in which instrumental behaviors were elicited, individuals with high M scores on the BSRI (Androgynous and Masculine individuals, according to the four-way categorical scheme) showed more of that type of behavior than did those low in M; similarly, in situations in which expressive behavior was appropriate, individuals high in F (Androgynous and Feminine) showed more of that type of behavior than did those low in F. Alone among the categorical groups, Androgynous subjects were thus high in both types of behavior. These data simultaneously provide evidence for the construct validity of the BSRI M and F scales as well as a behavioral demonstration of what was found in the correlational analysis of M and F self-report scores: namely, that it is possible to possess a high degree of both instrumental and expressive qualities.

In the Bem and Lenney (1976) study, a relation was determined between BSRI scores and preference for simple gender-related tasks whose performance had no discernible connection with instrumentality and expressiveness. Whether this study is relevant to the construct or predictive validity of the BSRI depends on one's theory. Bem apparently regards her instrument as a general measure of sex role preferences and behaviors. According to this theoretical conception of the BSRI, demonstration that Androgynous individuals show less sex typing in reaction to gender-related tasks than do other types of individuals (or that individuals who are sex typed are more sex typed in their task reactions) would thus fall into the category of construct validity. Our conception of the BSRI, and even more particularly of the PAQ, is that these measures primarily tap instrumental and expressive trait dispositions. Our theory further leads us to anticipate, at best, only minimal relation between M and F scores and the type of tasks devised by Bem and Lenney (1976). The evidence seems to favor the weak relation postulated by our theory rather than the strong ones postulated by Bem. While resolution of these rival views awaits additional data, the methodological point is clear: according to our theory, this type of experiment is addressed to predictive, not construct, validity. Negative results (i.e., failure to find a relation to behavior as a function of PAQ or BSRI scores) would strengthen the predictive validity of our theory but would not undermine the construct validity of these instruments, as we conceptualize them.

In commenting on our contention that the masculine and feminine characteristics tapped by the PAQ cannot necessarily be assumed to be highly related to other components of masculinity and femininity, Locksley and Colten note that it is "unsatisfactory to show that the . . . PAQ scales simply tap the traits they contain" (1979, p. 1028, Footnote 2). This is not the place to review a growing literature that shows the relation between the PAQ scales and a number of other types of self-report and behavioral measures (e.g., Helmreich & Spence, 1978; Klein, 1978; Spence & Helmreich, 1978). We note only that these

other measures sometimes show significant main effects for sex of subject and sometimes do not; when sex differences do occur, they often—but not universally—disappear when PAQ scores are taken into account. The instrumental and expressive characteristics measured by the PAQ show promise of contributing to our understanding of significant real-life behaviors, regardless of the gender of the individual in which they occur, and also of helping us to unravel some of the mysteries of sex differences.

One of our early findings, replicated numerous times with many types of samples, is that both M and F scores (but particularly the former) were positively correlated with a self-report measure of social competence and self-esteem. Androgynous individuals of both sexes —those relatively high in both M and F— scored highest, followed by Masculine, Feminine, and Undifferentiated. Similarly, we have found that clients of a student counseling center scored markedly lower on the M and F scales than unselected students did. We can find nothing that we have said about these data or about the rationale of the PAQ that would permit Locksley and Colten's curious conclusion that we regard these findings as support for the construct validity of our questionnaire.

We indicated above that empirical data gathered with the PAQ suggest that both the M and F scales are positively related to self-esteem and negatively related to neuroticism, anxiety, and other problem behaviors. Since M is more strongly correlated with the indices of adjustment than F, men and women classified as Masculine (high M, low F) receive scores that are only slightly different from those classified as Androgynous (high M, high F). Locksley and Colten, however, suggest that feminine characteristics are not merely more weakly related to adjustment than are masculine characteristics but that the relationship may be negative in direction, thus giving the edge to Masculine rather than to Androgynous individuals. In support of this claim, they cite a recent study by Jones, Chernovetz, and Hansson (1978), employing the BSRI, in which "masculine" subjects were found to have greater self-esteem, fewer neurotic and alcohol problems, and the like, than "androgynous" subjects had. The composition of these groups, however, was based on the now discarded subtractive method of scoring the BSRI, in which androgyny is defined as a balance between M and F, regardless of level, rather than as a relatively high degree of both M and F. However, Jones et al. (1978) went on to isolate groups of subjects who corresponded to our definitions of androgynous and undifferentiated subjects (above the median on both scales vs. below the median on both scales). Although not always significant, the means of indices of adjustment were uniformly higher in both sexes for the androgynous individuals than for the Undifferentiated individuals. What a comparison of Androgynous and Masculine groups would have shown is unknown. Even more troublesome, from our perspective, is the use of the BSRI rather than the PAQ. The BSRI F scale contains a number of items (some of which are listed by Locksley and Colten) that are not clearly expressive, communal traits, as we conceive of them, and/or, as we noted earlier, are socially undesirable for women as well as men. In our recent work with an expanded version of the PAQ that includes scales tapping masculine and feminine traits that are socially undesirable, we have found correlations with measures of neuroticism and acting-out behaviors that are opposite in sign for socially desirable and undesirable characteristics (Spence et al., in press).

It is also critical to note that we have not used the data indicating a positive relation between the socially desirable M and F scales and several measures of adjustment and self-esteem to predict that Androgyny (as defined by the PAQ) will always lead to the most "desirable" or "adaptive" behavior. Our reluctance is twofold. First, our empirical findings suggest that, whether considered separately or in combination, the M and F scales do not always relate to criterion variables in exactly the same way with respect either to magnitude or to direction. Therefore, the order of the categorical groups in terms of criterion responses does not always put Androgynous subjects at one end of a continuum and Undifferentiated subjects at the other. Further, as Locksley and Colten

(1979) note, terms such as "adaptive" or "effective" are often value laden and politicized. One example from our research will serve as an illustration. We have recently developed a multifactor measure of achievement motivation (Helmreich & Spence, 1978) that has demonstrated considerable construct and predictive validity. Significant differences in achievement-scale scores as a function of PAQ M and F category have also been found. For one of the scales, Competitiveness, the order in each sex is Masculine, Androgynous, Undifferentiated, and Feminine. Dependent on political philosophy, this result could be viewed as evidence for the superiority of the Androgynous individual over the Masculine—or the reverse. We have for these reasons rejected the denotations *androgyny researchers* or *androgyny theorists* as descriptions of our own efforts, writing:

> We are wary . . . of the surplus meaning, both ideological and empirical, that has accrued to "androgyny" as a label for the general model. . . . Our predictive model is . . . an open, evolving, dualistic one and in this sense is not "androgynous." (Spence & Helmreich, 1978, p. 109)

In suggesting a confusion between psychological and sociological levels of analysis, Locksley and Colten indicate that individuals who ignore sex-contingent expectations may do so at great cost and in this sense they may show behavior that is dysfunctional and maladaptive. Self-acknowledged androgyny theorists would be the first to admit, indeed insist, that this is true in contemporary society. In the long view, they argue that a society in which sex role distinctions were minimized would be healthier for all of its members. In the world of the here and now, they deny that those who fly in the face of traditional expectations on what Locksley and Colten describe as the sociological level are, on the psychological level, neurotic misfits, uncertain in their gender identification, sexually abnormal, and so forth. To the contrary, such individuals may be "healthier" than those who conform to conventional norms.

These speculations may well be valid. However, individuals who are androgynous in a role sense are not necessarily the same individuals who are androgynous on the PAQ or the BSRI. Data bearing on the hypotheses of androgyny theorists, to say nothing of Locksley and Colten's counterpropositions, have yet to be gathered.

Conclusions

From our theoretical perspective, the search for global measures of masculinity and femininity or sex role identity—measures that allow individuals to be placed along a quantitative dimension—is a snare and a delusion. The classes of psychological attributes and behavioral patterns that distinguish between men and women at a given time and a given culture are not only multitudinous but also may have different roots and may vary relatively independently across individuals. Still different findings may emerge when individuals' conceptions of their own masculinity or femininity are probed. There are many masculinities and femininities, and androgyny has many identities. The masculinity and femininity measured by the PAQ refers to a limited set of socially desirable instrumental and expressive personality traits, which are but one possible component of the global self-conceptions that Locksley and Colten discussed. Thus, from our theoretical vantage point, many of Locksley and Colten's methodological criticisms are rendered irrelevant. Androgyny on the level of sex role behaviors (the area of inquiry to which their critique is primarily directed) is a worthy topic of investigation that awaits the development of more appropriate measuring instruments than the BSRI or the PAQ.

Theory and Measurement of Androgyny: A Reply to the Pedhazur–Tetenbaum and Locksley–Colten Critiques

Sandra Lipsitz Bem
Cornell University

The theory behind both the Bem Sex Role Inventory (BSRI) and Bem's androgyny research, as well as particular issues raised in the critiques of Pedhazur and Tetenbaum and of Locksley and Colten, are discussed. It is noted that (a) the BSRI is based on a theory about both the cognitive processing and the motivational dynamics of sex-typed and androgynous individuals; (b) the strategy of item selection for the BSRI followed directly from the theory and utilized established techniques for test construction; (c) a short BSRI has been developed in accordance with the results of various factor analyses; (d) current research is testing the hypothesis that sex-typed and androgynous individuals differ in the extent to which gender serves as a cognitive schema; and (e) the concept of androgyny contains an inner contradiction and hence a built-in obsolescence.

The methodological critique of the Bem Sex Role Inventory (BSRI) by Pedhazur and Tetenbaum (1979) rests on a misunderstanding of both the purpose of the instrument and the theory underlying it. The more conceptual critique by Locksley and Colten (1979) reduces in most of its particulars to empirical questions about the generality of the concept of androgyny and about the domain of applicability of its associated measuring instruments. Accordingly, this response begins with an explication of the theory on which the BSRI is based, then proceeds to a discussion of some of the specifics of the Pedhazur–Tetenbaum critique, and ends with an overview of research currently in progress, research that ought to answer some of the questions raised by Locksley and Colten.

Preparation of this article was supported in part by National Science Foundation Grant BNS-78-22637 to Sandra Lipsitz Bem. The author would like to express her thanks to Daryl J. Bem for critical comments on the manuscript and to Richard Darlington for sharing his statistical expertise.

Requests for reprints should be sent to Sandra Lipsitz Bem, Department of Psychology, Uris Hall, Cornell University, Ithaca, New York 14853.

The Theoretical Rationale Behind the BSRI

The recent debate in personality–social psychology over the degree to which individuals show transituational consistencies in their behavior has led to the suggestion that we ought to reverse our usual assumption of consistency as given and inconsistency as problematic and, instead, adopt the view that it is the phenomenon of consistency that requires explanation (D. J. Bem, 1972). Such an approach shifts the burden of proof and leads us to ask why a person's behavior might display consistency rather than why it does not. Such an approach also suggests that behavioral consistency might itself be an important individual difference variable (e.g., Bem & Allen, 1974; Campus, 1974).

In the special case of sex roles, this shift of emphasis brings two idealized groups of individuals into focus: those "sex-typed" individuals who restrict their behavior in accordance with cultural definitions of sex-appropriate behavior, and those "androgynous" individuals who do not. This leads us for the first time to view the situational adaptability ("inconsistency") of the androgynous group

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3706-1047$00.75

as the "unmarked" norm—the given, the baseline—and to regard the sex-stereotyped consistency of the sex-typed group as "marked" or problematic, as the phenomenon to be explained.

Because the BSRI was developed to "capture" these particular groups of individuals, its construction was based on two specific theoretical assumptions: (a) Largely as a result of historical accident, the culture has clustered a quite heterogeneous collection of attributes into two mutually exclusive categories, each category considered both more characteristic of and more desirable for one or the other of the two sexes. These cultural expectations and prescriptions are well known by virtually all members of the culture. (b) Individuals differ from one another in the extent to which they utilize these cultural definitions as idealized standards of femininity and masculinity against which their own personality and behavior are to be evaluated. In particular, the sex-typed individual is highly attuned to these definitions and is motivated to keep her or his behavior consistent with them, a goal she or he presumably accomplishes both by selecting behaviors and attributes that enhance the image and by avoiding behaviors and attributes that violate the image. In contrast, the androgynous individual is less attuned to these cultural definitions of femininity and masculinity and is less likely to regulate her or his behavior in accordance with them. The BSRI is thus based on a theory about both the cognitive processing and the motivational dynamics of sex-typed and androgynous individuals. Moreover, empirical research on the behavioral correlates of sex typing and androgyny has so far confirmed that it is serving its intended conceptual purposes (cf. S. L. Bem, 1975; Bem & Lenney, 1976; Bem, Martyna, & Watson, 1976; Ickes & Barnes, 1978; Russell, 1978).

The Construction of the BSRI

The strategy utilized in the construction of the BSRI follows directly from these theoretical premises. Because the BSRI is founded on a conception of the sex-typed individual as someone who is highly attuned to cultural definitions of sex-appropriate behavior and who uses such definitions as the ideal standard against which her or his own behavior is to be judged, items for the BSRI were selected not on the basis of sex differences in self-report, as most previous masculinity–femininity inventories have been compiled, but on the basis of judges' ratings of the culturally defined desirability of various attributes for each of the two sexes. In contrast to self-reports on such items, these cultural definitions were expected to be widely known and to be quite stable across time and from sample to sample. The BSRI is thus designed to assess the extent to which the culture's definitions of desirable female and male attributes are reflected in an individual's self-description. More specifically, the BSRI presents an individual with a heterogeneous collection of attributes and assesses the extent to which the individual clusters this collection into the two categories designated by the culture as more desirable for one or the other of the two sexes.

In order to select items for the Femininity and Masculinity scales of the BSRI, undergraduate judges were asked to rate the desirability of approximately 200 personality attributes either "for a woman" or "for a man." No judge was asked to rate both. A personality characteristic was then defined as feminine or masculine (and hence eligible for the Femininity and Masculinity scales of the BSRI) if, and only if, it was judged to be significantly more desirable in American society for one sex than for the other by four independent samples of judges. The assumption that the culture's definitions of desirable female and male personalities are widely known implies that virtually any sample of American adults would be qualified to serve as knowledgeable informants with respect to these cultural definitions. Moreover, our instructions to the judges emphasized that we were interested not in the judges' personal opinions of how desirable these various attributes were but in their judgment of how American society would evaluate the various attributes. The consistency of the ratings across four independent samples of judges is strong evidence that the BSRI is tapping

widely known cultural definitions, as stipulated by the theory.

As Pedhazur and Tetenbaum (1979) point out, there has recently been a discussion in the literature as to how best to score the BSRI. When the BSRI was first developed, I set forth a definition of androgyny based on the *t* ratio between an individual's endorsement of feminine and masculine attributes, with small *t* ratios indicating androgyny and large *t* ratios (significant differences) indicating sex typing (S. L. Bem, 1974). This method of scoring the BSRI follows directly from the theory in that it distinguishes between those individuals who cluster the attributes on the BSRI into the two categories designated by the culture as more desirable for one or the other of the two sexes, and those individuals who do not. The later emergence of *behavioral* differences between those who score high on both the Femininity and the Masculinity scales (the androgynous high-highs) and those who score low on both (the "undifferentiated" low-lows)—even though both groups achieve small *t* ratios—led to the suggestion that the BSRI be scored on the basis of a median split on both dimensions, a scoring procedure yielding four rather than three distinct groups of individuals (S. L. Bem, 1977). For empirical purposes, this was an entirely sensible proposal, but it did tend to obscure the original theoretical rationale behind the BSRI.

The Pedhazur and Tetenbaum Critique

The BSRI as Atheoretical

The most pervasive criticism advanced by Pedhazur and Tetenbaum (1979) is that the BSRI is atheoretical: "Instead of defining the domains of masculinity and femininity and attempting to construct measures consistent with the definitions, Bem has chosen a strictly empirical approach" (p. 998), an approach that "was destined to fail" (p. 1012). The above discussion, however, contradicts Pedhazur and Tetenbaum's conclusion. The theory underlying the BSRI asserts that sex-typed individuals will conform to whatever definitions of femininity and masculinity the culture happens to provide. The theory deliberately does not specify the particular contents of these definitions, however, because these will vary from culture to culture. The theory is a theory of process, not content, and the use of judges as "native informants" about the particular contents of the culture's prescriptions flows directly from the theory itself. Contrary to Pedhazur and Tetenbaum, this is not dust-bowl empiricism.

Closely related to the criticism that the BSRI is atheoretical is the objection that the Femininity and Masculinity scales are not unidimensional, and that one should employ a methodology for constructing the scales that would guarantee their unidimensionality. But Pedhazur and Tetenbaum are putting the methodological cart before the theoretical horse. The culture has arbitrarily clustered together heterogeneous collections of attributes into the two categories prescribed as more desirable for one sex or the other. The very concept of androgyny is a positive assertion that these arbitrary clusters of apples and oranges need not—and for some individuals do not—"hang together." If the culture groups a hodgepodge of attributes into a category it calls "femininity" or "masculinity," then that hodgepodge is what sex-typed individuals will take as the standard for their behavior. The purpose of the BSRI is to discriminate between those individuals for whom this hodgepodge does form a unitary cluster and those individuals for whom it does not.

Multiple t *Tests as Inappropriate for Item Selection*

Pedhazur and Tetenbaum (1979) criticize the use of item-by-item *t* tests as the basis for item selection, presumably because of a concern that this strategy might capitalize on chance findings. They did not note, however, that the initial list of 200 personality characteristics was rated by four independent groups of judges and that an item was defined as feminine or masculine if, and only if, it was consistently and reliably rated as significantly more desirable for one or the other of the two sexes by all four groups of judges. The probability of this occurring by chance for any individual item is 1/160,000; the number of items out of 200 expected by

chance to reach significance in all four groups is .00125. Moreover, a recent replication at the University of Washington cross-validated this pattern for 37 of the 40 items on the BSRI (Walkup & Abbott, 1978). The results for the three exceptions were in the predicted direction, but reached significance only for female judges. Accordingly, the BSRI would appear to tap relatively enduring definitions of sex-appropriate behavior, culturally defined standards of sex-appropriate attributes that have not given way even in the face of a strong feminist critique in the culture at large. (The BSRI also contains 20 items that were judged by the original four samples of judges to be no more desirable in American society for one sex than for the other. The Walkup and Abbott replication cross-validated this "neutral" pattern for only about half of these items, a finding of little practical or theoretical significance because these items serve as filler and do not enter into the assessment of an individual's sex role.) [1]

Moreover, the use of item-by-item tests (whether *t* tests, *D*, or item-total correlations) is established practice in test construction (Anastasi, 1968), and it is the use of stepwise discriminant analysis that seems quite curious in this context. Because discriminant analysis weights each item only with respect to the amount of *incremental* discriminating power it has over and above the discriminating power of the items already entered into the equation, discriminant analysis is exceedingly sensitive to the composition of the particular items in the item pool. In the present case, for example, discriminant analysis would have yielded dramatically different weightings if the two items "feminine" and "masculine" had been excluded from the initial item pool, but the content of the culture's definitions would not have changed. Indeed, I suspect that even these two items would have been eliminated by a discriminant analysis if we had simply included the items "female" and "male" in the initial item pool. The goal of the social desirability ratings was to identify a comprehensive complement of items that the culture consistently and reliably designates as more appropriate for one or the other of the two sexes. Given this goal, it is simply not meaningful to conclude—as a discriminant analysis suggests we must—that only the two items "feminine" and "masculine" need to be considered.

In fact, there is now a body of accumulated evidence that suggests that—far from being the best two items on the scale—"feminine" and "masculine" are actually the worst two items on the scale. It is true, as Pedhazur and Tetenbaum (1979) point out, that these two items are responsible in large part for sex differences in self-report on the BSRI, but the goal of the BSRI is to measure and to facilitate the investigation of within-sex differences, not between-sex differences. The difference between females and males on the scales of the BSRI has never been used either as a criterion for item selection or as an indicator of validity (unlike the sex difference on Spence and Helmreich's Personal Attributes Questionnaire, 1978), but only as an empirical datum about a particular subject sample at a particular point in time. The theory behind the BSRI in no way commits itself even to the existence of a sex difference in any particular sample of women and men. Once again, the focus is on individual differences, not sex differences. Moreover, as factor analyses by Pedhazur and Tetenbaum and others (e.g., Berzins, Welling, & Wetter, 1978; Feather, 1978; Gaudreau, 1977; Waters, Waters, & Pincus, 1977) have indicated, these two items do not load highly with other items on the BSRI; rather, they form a bipolar factor of their own, a factor correlated

---

[1] It should be noted that an earlier study, also conducted at the University of Washington, had previously replicated this pattern for only 2 of the 40 attributes—"feminine" and "masculine"—a finding that was interpreted by the authors as indicating that the original social desirability ratings were not stable (Edwards & Ashworth, 1977). However, that study did not utilize our original instructions, but asked judges instead to rate "how desirable or undesirable you judge [each attribute] to be in an American male/female." In contrast, our instructions emphasized that we were only interested in each judge's assessment of how American society would evaluate the various attributes. The two kinds of ratings are simply not equivalent—in 1972 or 1977. The Edwards and Ashworth study thus constitutes a failure to replicate our methodology, not a failure to replicate our results.

in several analyses with gender. Finally, these two items are not highly correlated with their own total scale scores, but serve primarily as gender markers.

It is important in this context not to confuse the individual items "feminine" and "masculine" with the Femininity and Masculinity scales. The labels for the scales are a shorthand means of summarizing that all of the items were selected in the first place because they were judged more desirable either for women or for men.

Factor Analysis and the Short BSRI

As Pedhazur and Tetenbaum (1979) suggest, factor analyses of the feminine and masculine items on the BSRI generally yield four factors that account for 75% or more of the common variance: (a) a single feminine factor defined by such items as "warm," "gentle," and "eager to soothe hurt feelings"; (b) two masculine factors, one defined by such items as "dominant," "aggressive," and "assertive," and the other defined by such items as "independent," "self-reliant," and "self-sufficient"; and (c) a factor correlated in several analyses with gender and defined by the items "masculine" and "feminine" (and occasionally "athletic"). According to Pedhazur and Tetenbaum, these results are devastating to the BSRI. I disagree. Because the theory underlying the BSRI does not require that the domains of femininity and masculinity be unidimensional, it is only the existence of that small fourth factor that is unanticipated by the theory.

The results of these factor analyses do suggest ways in which the BSRI might be refined, however; and in fact, a short BSRI has recently been developed that contains exactly half of the original items. Two groups of feminine and masculine items in particular were eliminated during the development of the short BSRI: (a) The few items, including "feminine" and "masculine," that defined the factor correlated with gender, as noted above, and (b) a group of feminine items with relatively low social desirability, none of which correlated highly with the Femininity score or loaded on the feminine factor for either sex, and a few of which even had high loadings on the masculine factor (e.g., "yielding," "shy," and "soft-spoken"). These feminine items were included on the original BSRI in order to balance the overall social desirability of the feminine and masculine attributes, but as the concept of androgyny has evolved, it has seemed increasingly inappropriate to define androgyny in terms of these relatively undesirable attributes. Accordingly, the Femininity and Masculinity scales of the short BSRI consist of items that represent the most desirable personality characteristics for a given sex, and the variances of their social desirability ratings are quite comparable as well. Finally, the short BSRI also includes 10 filler items that were judged to be no more desirable for one sex than for the other in all four of our samples of judges as well as in the Walkup and Abbott (1978) replication.[2]

The Locksley and Colten Critique

In contrast to the critique by Pedhazur and Tetenbaum (1979), the Locksley and Colten (1979) critique raises strategic issues of a broader and more conceptual nature, issues that turn on the eventual heuristic payoff of differing approaches. For example, Locksley and Colten question the feasibility of basing the measurement of individual differences in femininity and masculinity on broadly based cultural stereotypes about women and men, and they believe that a more cognitive approach to sex typing would be more fruitful. Again, only future research can decide such issues. They also question the concept of androgyny itself: "Sex is an immediately perceptible feature of every person. . . . Considering the role of sex in the very architecture of experience and behavior, the notion of psychological androgyny, with its implication of freedom from sex-related social effects on personality and behavior, is arbitrary at best" (pp. 1028–1029).

But like most psychological concepts, the concepts of sex typing and androgyny are seen as matters of degree. I, too, would agree with

[2] A detailed manual for both the original and the short BSRI will soon be available from Consulting Psychologists Press, 577 College Avenue, Palo Alto, California 94306.

the rather unexceptional position that it is not possible for an individual to be completely free from sex-related social effects, but that does not preclude the possibility that individuals may differ in the extent to which gender serves as a cognitive schema for the processing of information, a lens through which they perceive and interpret social reality. Moreover, my current research on the cognitive processes mediating sex typing and androgyny is addressed to precisely this hypothesis.

Gender as a Cognitive Schema

The distinction between male and female clearly exists "out there" in the real world as a basic and fairly primitive dichotomy. Moreover, it is a dichotomy that is important to almost all human cultures in a way that extends well beyond basic biological differences in body build and reproductive function; and, precisely because it does loom so large, it is a dichotomy that cannot be overlooked or treated as psychologically irrelevant by anyone. Indeed, the distinction between male and female is known by children as young as 1 or 2 years of age, and in most cultures, children are explicitly taught to treat the gender dichotomy with seriousness and respect from that time forward. Moreover, within most cultures, a variety of different sources can aid and abet an individual's awareness of the gender dichotomy: for example, interacting exclusively with same-sex peers and inferring that the other sex must be fundamentally different from you; observing mothers and fathers in sex-stereotyped roles as homemaker and breadwinner and inferring that the two sexes must be fundamentally different from one another; observing that mixed-sex relationships always seem to have sexual overtones and inferring that heterosexual attraction constitutes the only experience shared in common by males and females; observing that different pronouns are used in reference to the two sexes and inferring that the distinction between them must be even more important than, say, the distinction between black and white or between young and old; and so forth.

But despite the universal recognition of the gender dichotomy, it is a basic assumption underlying my current research that there are wide individual differences in the functional importance attached to it. In particular, I hypothesize that sex-typed and androgynous individuals differ from one another in how much they believe the sexes to be basically different from one another—a belief in "gender polarity"—and that the differences between these sex-role groups both in self-description and in behavior are themselves a consequence of the differences in the content of their beliefs about the two sexes. Moreover, it is suggested that not only do individuals of different sex roles differ in the extent to which they hold different beliefs and expectations about what the two sexes are like but, furthermore, these beliefs mediate both how they, as individual males and females, behave and how they interpret the behavior of male and female others as well.

At the more basic level, it is hypothesized that individuals of different sex roles differ not only in the content of their beliefs about gender differences (gender polarity) but in their cognitive structures for coding and processing information as well, structures that have variously been called frames (Minsky, 1975), scripts (Abelson, 1976), and schemata (Bartlett, 1932; Bobrow & Norman, 1975; Kelley, 1972; Markus, 1977; Stotland & Canon, 1972). The notion of a schema connotes a highly articulated and dynamic concept that organizes and guides one's processing of information by virtue of its rich associative network, its implications for cause-and-effect relationships, and its well-developed criteria for making discriminations along the relevant dimensions, implying that individuals of different sex roles should differ in the cognitive processing of gender-related information. In particular, to the extent that an individual holds different beliefs about what the two sexes are like, information related to gender and to gender differences should be more perceptually salient and more cognitively available (Nisbett & Ross, in press; Ross, 1977; Tversky & Kahneman, 1973, 1974). That is, gender differences should be more readily perceived or noted; they should be more readily stored in and retrieved from

memory; they should be more readily used as the basis of personality attributions and predictive inferences; they should be more readily put forth as a causal candidate for a variety of behavioral outcomes. In short, the gender dimension should be more cognitively available for the processing of information. Accordingly, individuals of different sex roles are seen as differing in how much they spontaneously process information about the self, about others, and about the nonsocial environment in general in gender-related terms.

In sum, then, individuals of different sex roles are not viewed here as differing primarily in terms of how much masculinity or femininity they possess, but rather, they are viewed as differing more fundamentally (a) in the content of their beliefs about what the two sexes are like and (b) in their cognitive schemata for processing gender-related information, and hence in the perceptual salience and cognitive availability of gender and gender-related concepts as dimensions for processing incoming information.

It should be noted that two studies already in the literature provide preliminary support for the hypothesis that sex-typed individuals differentiate along a gender-related dimension significantly more than androgynous individuals do. In the first study, sex-typed and androgynous subjects watched either a female or a male on videotape performing a series of neutral activities, and, using a hand-held recorder, they segmented the videotaped sequence into self-defined units that seemed natural and meaningful to them. The results revealed a significant Sex Role × Sex of Actor interaction, with sex-typed subjects differentiating between the female and male actor significantly more than androgynous subjects did (Deaux & Major, 1977). In the second study, sex-typed and androgynous subjects rated the similarity of handwritings on masculinity–femininity, and they also rated the handwritings on an absolute scale of masculinity–femininity. The results indicated both that sex-typed subjects differentiated along the dimension of masculinity–femininity significantly more than androgynous subjects did and that they weighted it more heavily in making similarity judgments (Lippa, 1977).

Androgyny as a Transitional Concept

Locksley and Colten (1979) are rightly concerned with the conceptual status of the androgyny concept. As I have noted elsewhere, I have a discomfort of my own:

> If there is a moral to the concept of psychological androgyny, it is that behavior should have no gender. But there is an irony here, for the concept of androgyny contains an inner contradiction and hence the seeds of its own destruction. Thus, as the etymology of the word implies, the concept of androgyny necessarily presupposes that the concepts of femininity and masculinity themselves have distinct and substantive content. But to the extent that the androgynous message is absorbed by the culture, the concepts of femininity and masculinity will cease to have such content and the distinctions to which they refer will blur into invisibility. Thus, when androgyny becomes a reality, the *concept* of androgyny will have been transcended. (S. L. Bem, in press)

How Relevant is a Semantic Similarity Interpretation of Personality Ratings?

Jack Block, Daniel S. Weiss, and Avril Thorne
University of California, Berkeley

In recent years, a conceptual similarity interpretation of personality and interpersonal assessment ratings has been advanced by D'Andrade and Shweder. According to their view, such ratings are primarily understandable as linguistic artifacts having little or no connection with the real world. This position contravenes a central and widely used methodology of personality and behavior assessment. The present article critically evaluates the logic and data that have been used to support this conceptual similarity explanation and concludes that pertinent evidence is wanting. A primary finding of D'Andrade and Shweder, that judges can predict the intercorrelations among personality ratings, is shown in an experimental study to be an adventitious function of previously unrecognized patterns of redundancy in the personality variables that happen to have been used. Finally, some empirical relationships not assimilable to their position are noted together with some conceptual problems of their viewpoint.

A decade ago, D'Andrade (1965, 1974) began to advance a radical and sweeping critique of two essential techniques of personality assessment: personality ratings and personality questionnaires. Applying his own analytical logic to several sets of previously published data, D'Andrade concluded that "the correlations [among rating and inventory scales] are primarily an artifact of the rater's or the questionnaire taker's cognitive structure, and not a reflection of the real world" (1974, p. 181).

More recently, Shweder (1975, 1977a, 1977b) has extended and elaborated on D'Andrade's theme, asking the confronting question: "How relevant is an individual difference theory of personality?" (1975, p. 455). By "an individual difference theory of personality," Shweder referred to generally held conceptions of personality as epitomized, for example, by Child's (1968) definition: "More or less stable internal factors that make one person's behavior consistent from one time to another, and different from the behavior other people would manifest in comparable situations" (p. 83). Shweder answered his question negatively, boldly asserting that "an individual difference theory of personality" has been "shown" by him to be "no more than statements about how respondents [and psychologists] classify things as alike in meaning" (1975, p. 482). As Shweder noted, much of the evidence for the existence of personality parameters that shape behavior in coherent ways has depended on observation-based ratings and personality inventories. According to Shweder, when rating and inventory data are generated by psychologist-observers or by inventory takers, respondents (including psychologists)

> unwittingly substitute a theory of conceptual likeness for descriptions of behavioral co-occurrences. . . . Items alike in concept are inferred to be behaviorally characteristic of the same person even when, as is typically the case, conceptual relationships among items do not correspond to the actual behavioral relationships among items. . . . [As a result] these conceptually biased judgments create an "illusion" of underlying behavioral consistency which, although not apparent in actual behavior, deceptively validates the "individual difference" conceptualization of "personality." (1975, pp. 455-456)

This point of view, which strikes at the

very core of personality and behavioral assessment, has recently achieved appreciable currency, being approvingly cited in reviews by Schneider (1973) and Mischel (1968, 1969, 1973, 1977), among others. The present article is an effort to evaluate the premises, logic, and empiricism that underlie the strong conclusions of what we shall call the *conceptual similarity* position. We focus primarily on the "relevance" of personality ratings, a quite sufficient context in which to address the issues that have been raised.

The Conceptual Similarity Argument

Underlying the conceptual similarity position are several propositions and presumptions about personality assessment that require specification and scrutiny if the tenability of this conclusion is to be evaluated.

The Conceptual Similarity View of Personality and Behavior Assessment Research: Emphasis on Trait Similarity Structures

D'Andrade characterizes personality assessment as follows:

> First, one or more human observers are asked to judge one or more subjects on a number of traits of behavior; the judgments are expressed in ratings or rankings (scores) based on the observers' long-term (i.e., more than 10 minutes) memory of the subjects' behavior. Second, a single score is computed for each subject for each trait, usually by taking the mean of all the scores given to each subject for each trait. Third, to find out how the traits are related to each other, some measure of association, such as the product-moment correlation, is computed from the subjects' scores for all pairs of traits. Finally, the measures of association are analyzed to determine how the traits are organized with respect to each other . . . . The results of such analyses indicate which traits tend to go together, and the similarity structure of the trait measurements is taken as a representation of the structure or organization of the subjects' behavior. (1974, p. 161)

This impression of personality and behavioral assessment research will appear foreign to most assessment psychologists. Insofar as ratings are used as one of the primary methods of assessment, the first two steps listed by D'Andrade often apply. The rating data thus generated, however, are then generally used in a multipronged effort (together with other kinds of measures) to establish the construct validity of a concept. The goal of such effort is a dependable and coherent nomological network of relationships on which to base subsequent theorizing or prediction. The emphasis of personality research is, centrally, on the validity of the measures being used; that is, Do individuals earning different scores on an index also earn conceptually expectable different scores on entirely separate and independently formulated measures? There is a long history to this kind of effort; recent reviews of the status, accomplishments, and deficiencies of personality research are to be found in Block (1977a), Gough (1976), Hogan, DeSoto, and Solano (1977), and Stagner (1977).

The third and last steps listed in the D'Andrade (1974) conceptualization of personality research may, and often do, arise when multiple ratings or measures have been gathered and there is question or concern about the extent of redundancy of coverage of the personality or behavioral domain by the variables used. Although a certain amount of redundancy is required to ensure reliability, redundancy beyond this certain amount is wasteful. Various clustering methods, such as factor analysis, can be extremely useful in quickly and simply revealing the latent dimensionality of the set of ratings employed and as a guide to identifying rating variables that are dispensable with little, or at least acceptable, cost.

Although the results of factor analyses (and related methods) of sets of ratings are often of immediate and intrinsic interest, there are few personality psychologists today who would claim that obtained factor structures represent inexorable verities (cf. Lykken, 1971). It is now well recognized that by varying the mix of variables included in a clustering analysis, one can fundamentally alter both the number and nature of the summarizing dimensions subsequently obtained. Thus, D'Andrade's claim that "the similarity structure of the trait measurements is taken [by psychologists] as a representation of the structure or organization of the subjects' behavior" misunderstands both the analytical methods used and the views of most personality psychologists. Personality psychologists

seek or settle on useful sets of variables to be employed for the specification of the personal or behavioral qualities of the individuals to be studied. To the extent that the set of personality or behavioral variables has communal variance (i.e., is redundant), there will be a "similarity structure of the trait measurements." But such similarity structures represent neither conceptual nor empirical fixities. We believe that the focus on arbitrary and often adventitious "similarity structures" derived from ratings addresses tangential or subsidiary issues. Instead, we suggest that the essential concern of personality assessment—a concern not addressed by D'Andrade and Shweder—is the convergent and discriminant validity of personality and behavioral ratings. Moreover, we note that the validity of a personality measure is not necessarily tied to the interrelationships among a set of personality measures. We shall be returning to this point.

The Primary Demonstration of the Conceptual Similarity Position: Correspondence Between Rated Behavior and Conceptual Similarity Matrices

The personality or behavioral variables rated by observers or by peers to describe a set of subjects can be intercorrelated. We call the consequent matrix a Rated Behavior matrix. Separately, the variables that had been rated with respect to actual individuals can be scaled by judges for the degree of conceptual similarity or meaning equivalence each variable has with respect to every other variable. The resulting matrix of similarity indices we call a Conceptual Similarity matrix. The primary demonstration of the conceptual similarity position has been to show that for a number of previously published Rated Behavior matrices, the pattern of intercorrelations characterizing a Rated Behavior matrix could be well approximated by the pattern of intercorrelations characterizing the Conceptual Similarity matrix based on the same set of variables. Because of the frequently strong correspondence between these two matrices, in which the Rated Behavior matrix stems from observations of real individuals, whereas the Conceptual Similarity matrix derives from purely semantic judgments of the similarity of personality variables made without reference to palpable people, D'Andrade concluded that "with respect to personality and behavior specifications in the field of psychology . . . it is possible to confuse propositions about the world with propositions about language" (1965, p. 215). Shweder has been more vigorous in his assertions, claiming that

> Evidence generally thought to demonstrate the applicability of the "individual difference" conceptualization of "personality" [has been] shown to be equivocal by deriving the trait-factors discovered in interpersonal rating forms, questionnaire interviews and personality inventories from purely conceptual criteria without any reference to actual behavior. (1975, p. 459)

We suggest that the correspondence between a Rated Behavior matrix and a Conceptual Similarity matrix, when it exists, does not have the logical implication with respect to individual differences that the conceptual similarity position seems to claim. The reader should pause for a moment to verify that in no way whatsoever is it possible to proceed from the specific semantic similarity judgments on which the Conceptual Similarity matrix is based to a specification of just which individuals are rated high or low on a particular rating dimension. For example, to know that judges evaluate the personality rating variables "Introverted" and "Devaluates himself" as conceptually highly similar (Shweder, 1975, Table 1) is to be entirely uninformed about who is rated Introverted or as Devaluat(ing) himself or whether Introverted and Devaluates himself, as separate or conjoined variables, are important and useful characteristics in terms of which to classify people. We shall return later to this distinction between *classifying personality variables* as opposed to *classifying individuals in terms of personality variables.*

The Secondary Demonstration of the Conceptual Similarity Position: Absence of Correspondence Between Rated Behavior and Actual Behavior Matrices

From the beginning, D'Andrade recognized the confounded nature of the primary demonstration:

> It is possible that the so-called psychological traits

dealt with in this paper exist both as components in terms used to describe the external world and in the external world as well. Such an isomorphism, if it exists, might be the result of the external world affecting first the discriminations made by speakers of a language, who then eventually develop a semantic structure within the language to encode these discriminations. (1965, pp. 227–228)

Thus, the isomorphism hypothesis that "the semantic similarity of trait terms corresponds to the way these traits actually go together" (D'Andrade, 1974, p. 162) was confounded with the more dramatic systematic-distortion hypothesis "that traits the observer considers similar will be recalled as applying to the same person, even when this is not the case" (D'Andrade, 1974, p. 161).

To speak to the issue of confounding, D'Andrade (and Shweder) sought an additional demonstration that would distinguish between the two competing hypotheses. They reasoned that if the systematic distortion or conceptual similarity hypothesis was correct, a matrix of intercorrelations among what they called "actual behaviors" (which we will call the Actual Behavior matrix) should not correspond to the Rated Behavior or Conceptual Similarity matrices.

If the observer's memory-based ratings showed a very different pattern of correlations from that found for the data based on the actual behavior of the subjects (but a pattern similar to judgments of semantic similarity), it would be reasonable to reject the isomorphic hypothesis and to consider the systematic-distortion hypothesis supported. (D'Andrade, 1974, p. 162)

D'Andrade (1974) has reported on two studies in the existing psychological literature that he deemed to have Actual Behavior and Rated Behavior matrices suitable for unconfounding purposes; Shweder (1975) has reported a third study relating Actual Behavior and Rated Behavior patterns of intercorrelations to each other and to a Conceptual Similarity pattern. In all three sets of analyses, a strong conclusion is reached affirming the systematic-distortion or conceptual similarity interpretation:

Rated behavior is almost entirely under the influence of pre-existing conceptual schemes and corresponds to actual behavior relationships only to the extent pre-existing conceptual schemes happen to partially coincide with actual behavior. (Shweder, 1975, p. 462)

Later in this article, we shall suggest a number of reasons why the three studies located by D'Andrade and Shweder fail to meet their special hypothesis-testing requirements.

The Implications of the Conceptual Similarity Position

The critical import of the conceptual similarity argument is powerful, blunt, and devastating to personality psychology and other behavioral science fields relying on some form of ratings.

If the correlations on which these studies rest are primarily an artifact of the rater's or the questionnaire taker's cognitive structure, and not a reflection of the real world, there is little or no evidence that human behavior can be described by large multibehavior units. What remains is a world in which human behavior is to be described in terms of specific behaviors occurring in specific situations, as Mischel and others have argued. (D'Andrade, 1974, p. 181)

D'Andrade went on to suggest that "it is not necessary to group behavior into clusters, or traits, or dimensions to be able to give an economical description of an individual's behaviors" (1974, p. 184). Instead, he claimed that "a remarkably predictive description can be obtained" (p. 185) if one simply predicts the most frequent behavior previously observed in each of a number of different behavior settings. No data are offered with regard to the predictive efficacy of this behavior-specific approach. Whatever the predictive accuracy of this actuarial orientation may prove to be, it is clear that it abandons the elegance and economy of a theory of behavior. Many psychologists will not be interested in a psychology reduced to, and aspiring to no more than, an endless graphing of frequency distributions for behavior-category systems. Were the logic and empiricism surrounding the behavior-specific approach compelling, this reductionistic but assumption-free approach to "good prediction" would prevail. It is our contention, however, that the argument and evidence brought together to buttress the conceptual similarity interpretation of personality ratings as existing solely "in the eyes of the beholder" are

deeply flawed, wrongly focused, and greatly embarrassed by a host of empirical findings unassimilable to the systematic-distortion position.

The remainder of this article will more closely consider the evidence and reasoning underlying the conceptual similarity interpretation of the processes underlying personality assessment. We shall first evaluate the Actual Behavior – Rated Behavior matrix analyses intended to unconfound the isomorphic and systematic distortion hypotheses. Next, we go on to illustrate the conditions that are sufficient and perhaps necessary to create or to prevent correspondence between Rated Behavior and Conceptual Similarity matrices. Finally, we list a variety of connections between personality ratings and indisputably real world outcomes that cannot be understood in artifactual terms. In the course of our countering evaluation, we shall burden the reader with matters of analytic detail, psychometrics, and principles of inference. We do not apologize for the closeness of our analysis; too often in psychology, crucial experimental points and analytical considerations go unnoticed. If the reader is to form well-based opinions on the important issues involved, he or she will have to become actively involved in the specifics of the evaluative process.

Unconfounding the Isomorphic and Systematic-Distortion Hypotheses: Some Problems in the Analyses

To harden the case for a conceptual similarity interpretation of personality ratings, demonstrations were sought that

> Verbal data collecting procedures, such as interpersonal ratings, self-report inventories, and retrospective questionnaires, . . . cannot be systematically supported by detailed and immediately recorded observational data. (Shweder, 1975, pp. 459–460)

It was reasoned that

> Pattern comparison [of an Actual Behavior matrix with Rated Behavior matrices] is needed here because *it is not the validity of specific traits or categories which is in question* [emphasis added], but the validity of the correlations between traits. Ideally, for recording the actual behavior of the subjects, a mechanical device should be constructed to count frequencies of different kinds of behavior. Unfortunately . . . a mechanical measuring instrument is not practical at present for any judgment more complex than *is making noise* versus *is not making noise*. The closest approximation to a mechanical device appears to be a trained observer using a simple coding scheme to record a subject's behavior as it occurs. The immediacy of the observer's assessment and the simplicity of the coding decisions should, it is hoped, protect against systematic distortion of the type thought to take place in long-term (i.e., more than ten minutes) memory. (D'Andrade, 1974, p. 162)

The two studies reworked by D'Andrade for his Actual Behavior – Rated Behavior matrix comparisons are an investigation by Borgatta, Cottrell, and Mann (1958) and the doctoral dissertation of Mann (1959). Shweder has added a comparable analysis of a study by Newcomb (1929). It will be helpful to briefly characterize these studies.

The Borgatta et al. (1958) research used 47 graduates divided into five small groups. Each group met for ten 2-hour sessions to discuss "democratic leadership." During the ninth and tenth sessions, a *single* observer using the Interaction Process Analysis (IPA) category system (Bales, 1951) coded the ongoing interaction. Subsequently, for each member of the group, the rate of each Bales category was calculated. These rates served as the Actual Behavior scores for subsequent analysis. After the ninth session, each group member ranked all the members of his group with respect to 40 traits, 6 of which *approximated* the Bales categories. Subsequently, for each member, the average ranking (adjusted for the slight differences in group sizes) on each of the 6 traits approximating the Bales categories was calculated. These average rankings served as the Rated Behavior scores for subsequent analysis.

The Mann (1959) study used 100 fraternity undergraduates, each of whom was assigned to two different and nonoverlapping five-man groups. In one of these 50-minute groups, the group worked on a specific task; in the other kind of group, the group members attempted to formulate some fraternity policies. During each session, a *single* observer used a version of the Bales interaction categories to code the ongoing interaction. For each member of the group, the total

number of "acts" was calculated. For each of seven Bales IPA categories, the subject's act frequency was divided by his total number of acts to derive a percentage. These percentages served as the Actual Behavior scores for subsequent analysis. After a group session, each member rated the other four on 16 characteristics, 7 of which *approximated* the Bales-Mann interaction categories. Subsequently, for each subject, the sum of the ratings assigned by the other four members of his group on each of the characteristics was calculated. These pooled ratings served as one form of Rated Behavior scores for subsequent analysis. In addition, the interaction-observing coder at the end of each session was asked to rate directly for each subject the percentage of the subject's behavior in each of the Bales-Mann categories. These estimated percentages served as a second form of Rated Behavior scores in subsequent analysis.

The Newcomb (1929) study evaluated 51 problem boys (a group of 27 preadolescents and a group of 24 adolescents) attending a month-long summer camp. For each group, camp consisted of six tentfuls of boys, each tent supervised by a different counselor. Sometime during each day, for each boy, his tent counselor completed a behavior record with respect to 26 behavioral questions Newcomb asked because of their presumed relevance to extraversion–introversion. For each question, the counselor selected one of four alternatives provided by Newcomb, precoded as "positive" (i.e., implying extraversion) or "negative" (i.e., implying introversion). In subsequent tabulation for each boy, for each of the behavior questions the number of days on which a positive or a negative alternative had been recorded was divided by the total number of camp days for which a report had been submitted. These 26 proportions, from *single* and *uncalibrated* observers, served as the Actual Behavior scores for subsequent analysis. At the end of the camp period, a rating form on *approximately* the same 26 behavior situations was completed for each boy by his tent counselor and by five other counselors who had frequently observed each boy. The six ratings for each boy were then combined into one consensus rating. The 26 pooled ratings for each boy served as the Rated Behavior scores for subsequent analysis.

D'Andrade (1974) and Shweder (1975) suggest that the three studies just described permit them to "explicitly separate . . . the structure of 'social impressions' from the structure of behavioral instances" (Shweder, 1975, p. 479). We suggest, alternatively, that the reasoning and evidence adduced by D'Andrade and Shweder as support for this "separation" lack power and pertinence. Some of our concerns follow.

The categories or items or dimensions of behavior measured by the Actual Behavior indices are often different from those rated by observers. An analysis seeking to interpret the differences between the similarity structures derived from an Actual Behavior and a Rated Behavior matrix in conceptual similarity terms requires that the sets of variables being contrasted must, of course, be identical. The only data difference should be that in the Actual Behavior case, the variables are scored from "actual behavior," whereas in the Rated Behavior case, the variables are scored on the basis of retrospective judgments and inferences.

However, in none of the three studies used to demonstrate the difference between Actual Behavior and Rated Behavior matrices does the required equivalence obtain between the Actual Behavior and Rated Behavior sets of variables. Consider the following examples of failure of definitional comparability.

In the Borgatta et al. (1958) study, the Actual Behavior variable, IPA Category 1, is defined as "Shows solidarity, raises others' status, jokes, gives help, reward." The corresponding Rated Behavior variable is defined as "Shows solidarity and friendliness." Such facets of interaction as raising others' status, joking, and giving help and reward, included in the Actual Behavior version of this variable, are not included in the Rated Behavior version. The Actual Behavior variable, IPA Category 2, is defined as "Shows tension release, shows satisfaction, laughs." The corresponding Rated Behavior variable is defined as "Is responsive to laughter." Such facets of interaction as showing tension release and showing satisfaction, included in

the Actual Behavior version, are omitted from the Rated Behavior version. The Actual Behavior variable, IPA Category 4, is defined as "Gives suggestion, direction, implying autonomy for other." The corresponding Rated Behavior variable is defined as "Makes the most suggestions." The important qualifier, "implying autonomy for other," present in the Actual Behavior version, is absent from the Rated Behavior version. The remaining Actual Behavior – Rated Behavior correspondences pose similar problems of comparability.

In the Mann (1959) study, various Bales categories were merged. The first Actual Behavior variable, Mann's Category 1, subsumes showing solidarity (excluding all joking behavior) and showing agreement. The Rated Behavior version of this variable inquired "how much [the group member being rated] tended to agree with what others had said." No mention of solidarity is contained in the Rated Behavior variable definition, a most important omission.

Shweder's (1975) report of the Newcomb (1929) study claims that the same 26 items of behavior were evaluated by the daily records and by the end-of-camp ratings. In fact, 15 of the 26 items lack Actual Behavior – Rated Behavior identity. For example, the daily record item, "Was he fond of swimming?" becomes the rating item, "Did he spend his swimming period periods in the water, actively moving about?" The daily record item, "How much of the day did he spend doing things that required little or no action?" becomes the rating item, "Was he actively moving about most of the day?" Sometimes these differences seem slight but, as is well known, slight differences in phrasing often can have great effect.

The absence of exact equivalence between the definitions of the Actual Behavior and the Rated Behavior variable sets is regrettable; this consideration alone renders problematic the significance of subsequent Actual Behavior and Rated Behavior matrix comparisons that D'Andrade and Shweder have interpreted as evidence for the essential invalidity of "rated behaviors."

Emphasis solely on the correlations between traits ignores consideration of the validity of specific traits. We believe that most psychologists will indeed wish to know the specific validity of traits or categories—data deemed irrelevant by D'Andrade and Shweder. A moment of reflection will indicate to the reader that if the traits or categories being evaluated are validly measured, then the correlations between the traits or categories must be valid. However, the converse of this relationship does not apply; correlations between traits can exist and even be valid even though each trait is entirely invalid as a basis for ordering individuals.[1] Therefore, it is of interest to compare how similarly subjects are ordered by "rated behavior" scores and by "actual behavior" scores posited as the criterion for validity. In the Borgatta et al. (1958) study, the mean correlation between corresponding Rated Behavior and Actual Behavior variables is .25, with a range from .14 through .38. In the Mann (1959) study, the mean correlation of corresponding Rated Behavior and Actual Behavior variables is, for the Rated Behavior variables based on group member ratings, .33, with a range from .10 to .55. For the Rated Behavior variables based on ratings by the Actual Behavior coder, the mean Rated Behavior – Actual Behavior correlation is .41, with a range from .18 to .65. In the Newcomb (1929) study, the mean Rated Behavior – Actual Behavior correlation was .49, with a range from .16 to .73, for one group of boys, and .43, with a range from .02 to .68, for the second group of boys.

All of these figures warrant correction for attenuation due to the unreliability of the Rated Behavior and Actual Behavior measures (Block, 1963, 1964). However, unreliability of measurement is not noted as a factor operating to diminish the correspondence between Rated Behavior scores and Ac-

[1] As a simple physical illustration, consider a measure of height and a measure of weight and the consequent correlation between height and weight. If, for the sample of subjects involved, the paired scores for height and weight were to be randomly reassigned, the correlation between height and weight would be unchanged, but the validity of height and the validity of weight can be expected to be zero.

tual Behavior scores. Because the three studies provide no (or technically unsound) reliability coefficients, we cannot estimate what the relationships between the Rated Behavior and Actual Behavior variables would be if they were psychometrically improved. For many of the pairings, however, we can expect the correlation to increase appreciably.[2] Nevertheless, even as they stand, and recognizing the definitional discrepancies already noted, many of the Rated Behavior – Actual Behavior correlations cannot be considered low, especially when some of the additional attenuating factors to be introduced below are recognized.

The use of frequency counts of behavior is not a sufficient means of operationalizing complex psychological concepts. Conceptual similarity advocates recommend, "for recording the actual behavior of the subjects, . . . count frequencies of different kinds of behavior . . . using a simple coding scheme" (D'Andrade, 1974, p. 162). The several assumptions underlying this epistemological position are bothersome on several grounds.

1. D'Andrade and Shweder write as if "actual behavior" exists; it does not. Behavior in the raw has an infinite variety of facets and pattern possibilities and therefore can only be studied by selection. The act of selection, however done, represents a constructive and theoretical assertion about the world that wins its justification by the (ultimately personal) nomological network with which it subsequently can be surrounded. Kaplan (1964) has written tellingly regarding the philosophical issues in making the decision as to what to observe. More recently, Neisser (1976) has summarized various lines of evidence from cognitive psychology that indicate the human organism is an active, schematizing but also schemata-modifying being who only selectively connects with unencompassable "reality."

It should also be noted that the problems surrounding the notion of "actual behavior" cannot be escaped by shifting to a focus on "objective behavior." So-called "objective" measures of behavior of course can only reflect earlier decisions, sometimes not fully considered, as to where attention should be addressed. A conceptually inappropriate decision as to what aspect of behavior to select as an index of a psychological dimension cannot be redeemed by the subsequent impartiality of the coding of the irrelevant behavior. The scientific merit of "objective behavior" depends, finally, on the psychological incisiveness of what is being figured from the ground, not on the mechanicalness of recording.

What D'Andrade and Shweder appear to mean, then, by "actual behavior" are frequency counts or proportions summarizing arbitrary and narrow selections from the infinitely broad stream of behavior, observed by an individual who need make no inferences and who records the singled-out behaviors immediately. Such counts or proportions are viewed as an ultimate or at least sufficient criterion of truth—as being the benchmark against which all other data can be referenced and tested. However, we suggest that large problems assail even this more restricted view.

2. It is assumed that the Actual Behavior data are simple and direct in two senses: No pertinent behaviors are omitted, and no inference is required of the recording observer. Both of these assumptions are questionable. Interaction Process Analysis, used to provide Actual Behavior data in both of the studies offered by D'Andrade (1965, 1974), has been found to have many problems and is no longer viewed with the enthusiasm that surrounded it when first introduced (see Longabaugh, 1963; O'Dell, 1968; Waxler & Mishler, 1966). IPA coding is a taxing and inundating task: The solitary observer records "acts" continuously, typically at a rate of 10 to 20 scores per minute (Bales, 1968), observing *all* the members of the group for 50 minutes (in the Mann, 1959, study) or for 120 minutes (in the Borgatta et al., 1958, study), coding the onrushing stream of "acts" of group members into 12 supposedly sufficient, mutually exclusive, and by no means simple categories (7 categories in the Mann study) according to the particular

[2] For example, in the Mann (1959) study, a single 50-minute session is a doubtful basis on which to predict reliable Actual Behavior or Rated Behavior scores on five people on multiple characteristics.

"actor" involved. The task requires superhuman information-processing capacities; it is not surprising that flesh-and-blood IPA coders have not fared well when evaluated. Thus, whereas one IPA coder might record 10 acts during a particular minute, another coder might record 20. Because of the number of members in a group, the simultaneity of many "acts", and the differential and oscillating perceptions of observers, various group members receive slighted or unreliable recordings of their "acts." Over the interaction period, observers are often unable to sustain consistency in their codings. The IPA categories are widely criticized as being psychologically heterogeneous and requiring appreciable deliberation, awareness of context, and inference on the part of the observer. The reader should contemplate spending an hour or two watching 5 or 10 individuals, making decisions every 3 to 6 seconds, differentiating only between, for example, IPA Category 1 (shows solidarity, raises others' status, jokes, gives help, rewards), Category 2 (shows tension release, shows satisfaction, laughs), and Category 3 (agrees, shows passive acceptance, understands, concurs, complies). Is an act involving humor a "showing of solidarity" or a "showing of tension release"? Is a remark a "reward" (Category 1) or a "showing of satisfaction" (Category 2)? Certainly, Interaction Process Analysis can provide useful data of a kind. But the technique is highly complicated and is subject to many kinds of problems or vitiating influences often not recognized in the early IPA studies now used unquestioningly by D'Andrade. We suggest that few psychologists will award IPA-based data deferential status as a criterion.

The Newcomb (1929) "behavior records" offered by Shweder (1975) as "actual behavior" also cannot be viewed as involving a sufficiently inclusive and noninferential set of coding rules. Rather, the recording counselor was compelled to make delayed and highly complex judgments with respect only to the categories afforded by Newcomb; behavioral observations not codable into Newcomb's categories could not be registered. By way of illustration, consider Behavior Record Situation 1: "Did [the boy] show confidence in his own abilities?" Newcomb defined four "degrees of response to this situation"; (a) "Boasted loudly of greater abilities than he had"; (b) "Spoke confidently of abilities he really had"; (c) "Expressed lack of confidence in own abilities"; and (d) "Hesitated even to try his ability" (p. 21). It is immediately obvious, when the full text of the categories available to the counselors is referenced, that the superordinate questions (regarding "confidence," "initiative," etc.) asked of them required appreciable psychological inference before the "behavior record" could be completed. Such characteristics as "speaking confidently of abilities one really has" or being "loyal to the leader" are not so behaviorally denotable as to require little human judgment. Also, only one counselor completed the behavior record for each boy, and the extent to which another counselor would have completed that record in the same way is nowhere assessed.

We intend no disparagement of the Newcomb study of a half century ago, a study that for its time was in many ways exemplary. We do suggest that because of the presence of appreciable psychological inference in the behavior records, the sharp distinction necessary between "actual behavior" and "rated behavior" is, instead, blurred.

3. In the IPA studies cited by D'Andrade (1965, 1974) and in the Newcomb study reused by Shweder (1975), "actual behavior" was finally indexed in one of three ways: rate of emission of certain categories of behavior, act percentages, or the percentage of days on which a categorized behavior had been noted. All of these indices of "actual behavior" involve some form of averaging over behavioral instances. Behavior averaging is a very useful technique, but the indices so derived are insensitive to behavior context and the relative salience of any particular instance of coded behavior. All occurrences of a coded act are equally weighted in the "actual behavior" averaging. Thus, in Newcomb's study, a boy who began the camp session as shyly noninteractive and ended up as comfortably gregarious could well earn the same percentage score on the *interaction* dimension as another boy who began camp as aggressively interactive and

became a rejected isolate by the end. The behavior percentage scores used to reference "actual behavior" are logically unable to index such change. On the other hand, the "rated behaviors" in the Newcomb study have the possibility of expressing such changes as may have occurred. Making their ratings at the end of the camp session, the raters had the opportunity to express their integration of all of their understandings of each boy, including such contextual or sequential or salience effects as they believed to be pertinent. In short, useful though the averaging basis underlying the "actual behavior" scores may generally be, such scores may not be able to capture important information and recognitions codable by raters who use long-term memory. Besides the possibility of "systematic distortion" emphasized by D'Andrade (and Shweder) when raters invoke long-term memory, there is also the possibility that raters will be able to discern relationship, meanings, and trends that were denied identifiability in the highly summarizing "actual behavior" averages. Again, we suggest that most personality psychologists will not accept such averages uncritically as a criterion of "actual behavior."

Extraneous influences distorting correlation coefficients and their patterning are not considered. Many factors influence individual correlation coefficients and, thus, the subsequently organized matrix of correlation coefficients. Sometimes these coefficient-influencing factors are not of great importance vis-à-vis the broad questions being asked of the data. But when conclusions hinge on the particular values of particular pattern-making or pattern-breaking coefficients, these considerations become crucial to evaluate and to control. Yet, when D'Andrade and Shweder contrast matrices, they ignore the many psychometric and statistical considerations that influence the observed differences in correlational patterning.

1. The distributions of the Actual Behavior scores and the Rated Behavior scores are not considered. They are often likely to be highly skewed or not unimodal, particularly the IPA rates or percentages representing "actual behavior." Correlations between variables are importantly influenced (and always lowered) by differences in the shapes of the distributions being related (Carroll, 1961).

2. The logic by which IPA "actual behavior" scores are generated for each subject necessarily creates an appreciable degree of *negative* correlation among IPA "actual behavior" scores.[3] The degree of negativity increases as the number of IPA categories decreases; especially affected is the Mann (1959) 7-category IPA system. Although the entailed negative relation among IPA "actual behavior" scores does not uniformly depress the intercorrelations among such IPA scores, the average intercorrelation among these IPA scores will be moved toward negativity by this influence. The interpretation by D'Andrade (1974) of the generally lower intercorrelations among his Actual Behavior matrices as compared to his Rated Behavior matrices does not recognize this lowering effect on the Actual Behavior coefficients.

3. The Actual Behavior data used were derived from only one observer-recorder; four of the five sets of Rated Behavior data were based on pooled judgments from a number of observers. Ceteris paribus, data from a single observer are less dependable than data derived by pooling the data from a number of observers. D'Andrade and Shweder did not consider that to an extent unassessable within the data they used, the discrepancies between their Actual Behavior and Rated Behavior scores and consequent matrices are a function of this source of unreliability in the Actual Behavior data.

4. D'Andrade's IPA analyses involve six or seven IPA categories or variables. Six or seven variables generate, respectively, 15 or 21 coefficients of correlation. The correlation of these Actual Behavior coefficients with corresponding Rated Behavior coefficients yields intermatrix correlations based on *n*s of 15 or 21, extremely small "sample" sizes.

---

[3] Because an individual's IPA category scores are calculated with reference to his total number of acts, the resulting scores are like slices of a pie—as one slice becomes large, the remaining slices are constrained to be small. Guilford (1952) has warned of the dangers of misinterpreting correlations among such reciprocally dependent scores.

Furthermore, *these 15 or 21 "observations" are not independent of each other;* the correlation between Categories X and Y and the correlation between Categories X and Z will constrain the correlation between Categories Y and Z. The distribution of nonindependent observations will tend to be strange and unstable, reacting strongly to changes in the constitution of the set of six or seven categories that happen to have been used. Correlations based on nonindependent observations are not correlations in the usual sense of the term, since the interdependency of observations violates a fundamental assumption of the statistical logic underlying the correlation coefficient. One can no longer interpret such fluky coefficients in terms of amount of variance explained or significance level. The correlation between two correlation matrices has a certain descriptive value, but the intuitive appreciation of these coefficients requires the further recognition that these coefficients are indeed of an unspecifiable but certainly bizarre metric.

5. The direction of scoring or rating a psychological variable is usually arbitrary; one can algebraically reflect a variable without changing its conceptual import. Instead of assigning high numbers to indicate "extroversion," we could as well assign high numbers to mean "absence of extroversion." This long-established recognition has severe implications for the "correlation" between two matrices.

Changes in the direction in which a variable is scored reverse the signs of the correlations of that variable with other variables and will fundamentally influence the "correlation" subsequently computed between these revised matrices (Tellegen, 1965). In the D'Andrade and Shweder analyses, bipolarities tended to characterize their redundancies of measurement. Had the variables defining one end of their dimensions been defined instead in reflected terms, the subsequent correlation matrix would have had fewer negative entries and the "correlation" between correlation matrices would have been importantly smaller. Thus, in yet another way, the results of these analyses are shaped by adventitious aspects of the data.

6. The preceding psychometric recitative has listed seriatim a number of concerns about the D'Andrade and Shweder numerical analyses. Their influence, in the aggregate and in interaction, are beyond ready evaluation, but can be expected to be appreciable.

What can be concluded from the D'Andrade and Shweder reanalyses seeking to unconfound the conceptual similarity interpretation from the isomorphism view? D'Andrade reported a correlation of .34 between the Actual Behavior and Rated Behavior matrices in the Borgatta et al. (1958) study; for the Mann (1959) study, he reported Actual Behavior – Rated Behavior matrix intercorrelations averaging .02 and .24 for the pooled judgment and individual observer Rated Behavior matrices, respectively. Shweder (1975) reports Actual Behavior – Rated Behavior matrix intercorrelations of .51 and .38. Given the psychometric, definitional, conceptual, and methodological problems affecting the comparison of the Actual Behavior and Rated Behavior matrices, we suggested that it is impossible to view these "coefficients" as compelling of any interpretation at all. Instead of being impressed that these "coefficients" are so low, one can as well be surprised that they are so high.

Controlling the Correspondence of Rated Behavior and Conceptual Similarity Structures

The primary demonstration of the conceptual similarity position has been to show that a variety of previously published Rated Behavior matrices or analyses of Rated Behavior matrices are in strong correspondence with Conceptual Similarity matrices or analyses of Conceptual Similarity matrices that are entirely separately generated. D'Andrade and Shweder view the observed correspondence between the Rated Behavior and Conceptual Similarity matrices they have examined as an invariant and widely generalizable datum demanding recognition in their own preferred terms. In disagreement, we suggest that the correspondences noted are a previously unrecognized function of the high redundancy and the structure of that redundancy that just happened to be present

in the particular variable sets D'Andrade and Shweder sampled.

By varying the amount and structure of variable redundancy, thus influencing the extent and pattern of intercorrelations among variables, we have been able to manipulate the subsequent degree of correspondence between Rated Behavior and Conceptual Similarity matrices. Our logical demonstration, together with the recognition of the kinds of redundancy present in the variable sets evaluated by D'Andrade and Shweder, diminishes the implicativeness of their findings.

Method

A Demonstration of the Workings of Redundancy

For our manipulational purposes, a set of personality variables was required from which subsets could be selected that met specified redundancy designs. The California Q-set (CQ-set; Block, 1961, 1971), a broadly ranging set of personality-descriptive items, was used because of its extensive use in personality assessment and because of its multidimensional characteristics. The CQ-set had been used as a basic personality description procedure in a longitudinal study of personality development (Block, 1971). In this study, the personality characteristics of 76 men and 84 women were assessed by means of the CQ-set at three time periods: junior high school, senior high school, and adulthood (when the subjects were in their mid-thirties). Assessment for each time period was by (usually) three clinical psychologists, an entirely different set of psychologists being used for each time interval. Each psychologist formulated his or her description of a subject entirely independently of the judgments by the other psychologists. Furthermore, the information made available for a particular time period was entirely independent of the information made available for the other time periods. For each time period, the multiple CQ-set formulations of a subject's personality were averaged; it is these averaged ratings that serve as our Rated Behavior scores. Over the three time periods, there were 90 common personality variables, equivalently evaluated. The reader is referred to the original report for further details and for information on the various "quality controls" used during the prolonged process of generating these data.

The Rated Behavior data from the middle time period, senior high school, were selected and, for the sexes combined ($N = 160$), the 90 CQ variables were intercorrelated and factor analyzed. The principal components solution was rotated to a varimax criterion, yielding 15 orthogonal factors. The resulting factor loading matrix provided the basis on which selection of stimulus items was made.

Three sets of 12 items each were selected. The first set of CQ items was chosen on the basis of their high loadings, either positive or negative, on the first factor. The 12 items, 6 positive and 6 negative, had a mean first factor loading, disregarding sign, of .73 (all calculations averaging correlations used Fisher's r-to-z transformation). These 12 CQ items represent a *unidimensional* and *bipolar redundancy* and will hereafter be called the Unidimensional, Bipolar Redundancy variable set. The 66 intercorrelations among these 12 variables constitute a Unidimensional, Bipolar Redundancy Rated Behavior matrix. For each of the three time periods, and for each of the sexes, the Unidimensional, Bipolar Redundancy Rated Behavior matrices were calculated.

A second set of 12 CQ items was chosen to represent the first, second, and fourth orthogonal factors. For each factor, four CQ items, two loaded highly positively and two loaded highly negatively, were selected. The average factor loading of these 12 items (vis-à-vis their respective factors and disregarding sign) is .75. These 12 CQ items represent a *multidimensional* and *bipolar redundancy* and will hereafter be called the Multidimensional, Bipolar Redundancy variable set. The 66 intercorrelations among these 12 variables constitute a Multidimensional, Bipolar Redundancy Rated Behavior matrix. The six Multidimensional, Bipolar Redundancy Rated Behavior matrices (derived from the data on three time periods and both sexes) were calculated.

The third set of 12 CQ items was chosen so that each item represented 1 of 12 orthogonal factors. Some of the later factors extracted are defined by only a few CQ items. In selecting an item to represent a factor, some attention was paid to the item's loadings on the other 11 factors so as to preserve item orthogonality but, because of the restrictions on possible item choices, the items finally selected to represent the 12 factors can be said to only *approximate orthogonality*. Each item had a factor loading on its respective factor of at least .62, the mean of these factor loadings being .78. The mean loading of the items representing the last 11 factors with respect to the first factor was .16. We shall call this third set of CQ items the Approximately Orthogonal variable set. The 66 intercorrelations among these 12 variables constitute an Approximately Orthogonal Rated Behavior matrix. The six Approximately Orthogonal Rated Behavior matrices were calculated.

The three sets of variables selected are presented in Table 1.

Within each variable set, each CQ item was paired with every other item, the 66 pairings being typed onto index cards. Each deck of 66 cards was given to conceptual similarity judges with the following instructions:

The purpose of this research is to obtain judg-

Table 1
California Q-Set Items Constituting the Three Variable Sets

Items constituting the Unidimensional, Bipolar Redundancy set
4. Is a talkative individual.
17. Has a rapid personal tempo; behaves and acts quickly.
40. Is facially and/or gesturally expressive.
49. Behaves in an assertive fashion in interpersonal situations.
50. Tends toward undercontrol of needs and impulses; unable to delay gratification.
89. Is self-dramatizing; histrionic.
22. Tends toward overcontrol of needs and impulses; binds tensions excessively; delays gratification unnecessarily.
37. Is vulnerable to real or fancied threat, is generally fearful.
39. Reluctant to commit self to any definite course of action; tends to delay or avoid action. (Uncharacteristic end indicates quick to act.)
45. Aloof, keeps people at a distance; avoids close interpersonal relationships.
72. Tends to ruminate and have persistent, preoccupying thoughts (either pathological or creative).
87. Is emotionally bland; has flattened affect.
Items constituting the Multidimensional, Bipolar Redundancy set
4. Is a talkative individual.
17. Has a rapid personal tempo; behaves and acts quickly.
45. Aloof, keeps people at a distance; avoids close interpersonal relationships.
87. Is emotionally bland; has flattened affect.
24. Shows condescending behavior in relations with others.
33. Is subtly negativistic; tends to undermine and obstruct or sabotage.
5. Behaves in a giving way toward others.
15. Behaves in a sympathetic or considerate manner.
42. Has a brittle ego-defense system; has a small reserve of integration; would be disorganized and maladaptive when under stress or trauma.
52. Is self-defeating.
23. Is productive; gets things done.
67. Is consciously unaware of self-concern; feels satisfied with self.
Items constituting the Approximately Orthogonal set
7. Appears to have a high degree of intellectual capacity (whether actualized or not). (Originality is not necessarily assumed.)
12. Is thin-skinned; vulnerable to anything that can be construed as criticism or an interpersonal slight.
17. Has a rapid personal tempo; behaves and acts quickly.
24. Shows condescending behavior in relations with others.
43. Engages in personal fantasy, daydreams, and speculations.
56. Is concerned with own body and the adequacy of its physiological functioning. (Body cathexis.)
62. Enjoys aesthetic impressions; is aesthetically reactive.
68. Has a clear-cut, internally consistent personality. (Amount of information available before sorting is not intended here.)
73. Interested in members of the opposite sex. (At opposite end, implies absence of such interest.)
74. Is physically attractive. (The cultural criterion is to be applied here.)
85. Tends to offer advice.
86. Values own independence and autonomy.

ments of the similarity between self-descriptions. Each pair of descriptions is on a card. To familiarize yourself with the task, spread the cards out and skim through them. Then, taking the cards in any order you wish, read the two descriptions on a card and decide how *conceptually alike* are the two self-descriptions. Make each judgment according to the following scale, placing each card in the pile corresponding to your judgment: 7 = extremely similar; 6 = moderately

similar; 5 = mildly similar; 4 = unrelated, neither similar nor dissimilar; 3 = mildly dissimilar; 2 = moderately dissimilar; 1 = extremely dissimilar.

These instructions were adapted from those previously employed by D'Andrade and Shweder.

For the Unidimensional, Bipolar Redundancy variable set and the Multidimensional, Bipolar Redundancy variable set, 10 judges each made similarity judgments. For the Approximately Orthogonal set, 20 judges were used. No judge rated more than one variable set. The judges were undergraduates in a course on the psychology of personality and were uninformed as to both the nature and the purpose of the study. Two of the 20 judges of the Approximately Orthogonal variable set did not correctly complete the task, reducing this final total to 18.

Results

The 66 judgments of conceptual similarity by a judge is his or her Conceptual Similarity matrix. When the individual Conceptual Similarity matrices of the Unidimensional, Bipolar Redundancy judges are correlated with the six Unidimensional, Bipolar Redundancy Rated Behavior matrices, the average Conceptual Similarity – Rated Behavior intermatrix "correlation" is .63, ranging from .18 to .93. When the individual Conceptual Similarity matrices of the Multidimensional, Bipolar Redundancy judges are correlated with the six Multidimensional, Bipolar Redundancy Rated Behavior matrices, the average Conceptual Similarity – Rated Behavior intermatrix "correlation" is .50, ranging from −.11 to .75. When the individual Conceptual Similarity matrices of the Approximately Orthogonal judges are correlated with the six Approximately Orthogonal Rated Behavior matrices, the average Conceptual Similarity – Rated Behavior intermatrix "correlation" is .21, ranging from −.13 to .46.[4] As expected, the mean Conceptual Similarity – Rated Behavior "correlations" of the Unidimensional, Bipolar Redundancy and Multidimensional, Bipolar Redundancy groups are not significantly different ($t = .90$, $p < .38$). When the Unidimensional, Bipolar Redundancy and Multidimensional, Bipolar Redundancy judging groups are combined and contrasted with the Approximately Orthogonal judging group, the difference between their respective mean Conceptual Similarity – Rated Behavior intermatrix "correlations" is highly significant ($t = 5.17$, $p < .00001$). Thus these data reveal, strikingly, that Conceptual Similarity – Rated Behavior intermatrix correspondence is high when bipolar redundancy is high and is low when bipolar redundancy is low. Judges appear to be rather faithful reflectors of the pattern of redundancy empirically existing within the set of variables they are evaluating for conceptual similarity.

As a related finding, the average intermatrix "correlation" among the Conceptual Similarity matrices contributed by the 10 Unidimensional, Bipolar Redundancy judges was .41. The average "intercorrelation" among the Conceptual Similarity matrices of the 10 Multidimensional, Bipolar Redundancy judges was .36. The average "intercorrelation" among the Conceptual Similarity matrices of the 18 Approximately Orthogonal judges was .21. Thus, it appears that the ability of judges to agree among themselves in their judgments of conceptual similarity is a clear function of the pattern of redundancy present among the variables being evaluated.

Redundancy in the Variable Sets Evaluated by D'Andrade and Shweder

The pertinence of our demonstration of the influence of redundancy on the "correlation" between Rated Behavior and Conceptual Similarity matrices depends on the extent to which the amount and pattern of redundancy, previously unrecognized as operative, characterizes the variable sets previously found to be "retrievable" by Conceptual Similarity judgments.

Inspecting the variable sets that have been used, it is clear, we suggest, that appreciable and highly patterned redundancy does indeed characterize them.

The 20 personality terms of Norman (1963), further analyzed by D'Andrade (1965), were a carefully refined and well-

[4] It should be noted that the generally small but consistent loadings of the Approximately Orthogonal variables on the first factor contribute to the mean Conceptual Similarity – Rated Behavior intermatrix correlation of .21.

studied variable set intended to provide redundant specification of an orthogonal five-factor structure deemed conceptually suitable for encompassing peer-nomination data. Our Multidimensional, Bipolar variable set was designed to emulate the redundancy design built into the Norman terms.

The six rated variables in the Borgatta et al. study were included in a factor analysis (1958, Table 3). Four of the variables loaded highly on their first interpersonal factor; the remaining two loaded highly on their second factor. Our Multidimensional, Bipolar variable set approximately represents the redundancy characteristics of the Borgatta et al. set of rated variables.

The six (or seven) rated variables in the Mann (1959) study were not submitted to a factor analysis but, since they parallel closely the variables used by Borgatta et al., it is probably safe to assume that the pattern of redundancy characteristic of the earlier study also characterizes the later study.

The 26 variables used by Newcomb (1929) were not and cannot now be studied empirically with regard to their redundancy characteristics. However, because Newcomb selected his variables for their presumed relevance to the single broad dimension of extroversion–introversion, we suggest that appreciable redundancy of the unidimensional, bipolar type characterizes the Newcomb variable set.

The three other variable sets whose matrices are reported by Shweder (1975, 1977a) to be "retrievable" via conceptual similarity judgments—those of Bales (1970), of Sears, Maccoby, and Levin (1957), and of Block (1965)—all were factor analyzed, as reported in their initial publications, and all manifested appreciable redundancy of the multidimensional, bipolar, or unidimensional, bipolar type, according to the investigators' measurement intentions.

Thus, bipolar redundancy within the variable sets appears to be a strong and constant feature of the D'Andrade and Shweder analyses. This bipolar redundancy is generally antonymic (and synonymic) in nature, thus offering a semantic basis to judges for estimating, if only approximately, the nonzero correlations among various pairs of variables in the set. To the extent that Rated Behavior variables are measured validly but not with antonymic (and synonymic) redundancy, the possibility of correspondence ("retrievability") between a Rated Behavior and a Conceptual Similarity matrix tends to disappear because the "similarity structure" of each matrix tends to disappear. The external validity of the variables in the variable set, either singly or as subsets, is in no way contingent on the "retrievability" or the absence of "retrievability" of a Rated Behavior matrix by a Conceptual Similarity matrix. To this last concern—the predictive and concurrent validity of personality ratings—we now turn.

Some Empirical Relationships Currently Beyond the Reach of the Conceptual Similarity Position

For assessment psychologists, a frustrating aspect of the current controversy has been the narrowly delineated arena in which the argument has been waged. In this section we introduce some relationships of a kind that personality psychologists find reinforcing of their belief in reliable individual differences with regard to personality parameters of consequence in the real world. We believe the kinds of across-time or across-domain relationships to be reported are either unassimilable to the conceptual similarity interpretation or else are encompassable only by a string of conjectures so complicated and tenuous as to deprive the conceptual similarity view of interest until such time as the necessary empirical support becomes available. Our strategy for affirming the usefulness and even the necessity of the conceptual–empirical enterprise of personality requires even the necessity of the conceptual–emphasis on *classifications of personality variables*. We focus instead on the construct validity of *classifications of individuals with respect to personality variables*. Space limitations permit only brief citation of some of the available data confronting the conceptual similarity position.

The six Approximately Orthogonal Rated

Behavior matrices could not be well "retrieved" by the Approximately Orthogonal Conceptual Similarity matrix. By the reasoning of D'Andrade and Shweder, it follows therefore that "an illusion of . . . behavioral consistency" (Shweder, 1975, p. 456) was *not* created by the conceptual similarity among the personality variables involved simply because there was not appreciable "conceptual likeness" among the variables being evaluated. If there is behavioral consistency nevertheless, such consistency is not illusory.

The "behavioral consistency view" or "individual difference theory of personality," as defined by Shweder (and as rejected by him), assumes that an individual's behavior will tend to be "consistent from one time to another, and different from the behavior other people would manifest" (Child, 1968, p. 83). A direct test of behavioral consistency is the correlation of a Rated Behavior variable as rated at one time with the same Rated Behavior variable as independently rated at another time.

For the 12 Approximately Orthogonal Rated Behavior variables, across-time correlations are available, for the sexes separately, connecting the junior high school (JHS) and senior high school (SHS) ratings (a period of 3 years), connecting the SHS and Adulthood ratings (a period of about 20 years), and connecting the JHS and Adulthood ratings (a period of about 23 years). It should be recalled again that these ratings were based on entirely independent sets of data and entirely independent sets of judges.

For the male and female samples from JHS to SHS, the 12 Approximately Orthogonal rated variables correlate, on the average, .42 and .40, respectively. If these correlations are adjusted for their attenuation due to unreliability, the mean correlations rise to .68 and .66. From SHS to Adulthood, the average correlations are .27 and .30 for the two sexes, respectively. Adjusted for attenuation, these mean correlations become .41 and .49. From JHS to Adulthood, the average correlations are .24 and .28 for the two sexes, respectively. Adjusted for attenuation, these mean correlations are estimated to be .36 and .46. It should be noted that the 12 variables for which across-time person-ordering consistency is reported were *not* selected for consideration because of the across-time consistency they manifested. Many more such across-time correlations exist, the full set being reported by Block (1971). It should also be recognized that these across-time correlations are further and appreciably lowered by such developmental changes and transformations as take place from early to late adolescence and from late adolescence to the mid-thirties.

All things considered, we suggest that these across-time correlations are substantial evidence for the existence of sufficient behavioral consistency in sufficient people over sufficient time to warrant maintenence of "the individual difference theory of personality." A close and empirically supported explanation of these and related data in conceptual similarity or other attributional terms has yet to appear.

In seeking to dispense with personality ratings and personality inventories on the basis of their conceptual similarity arguments and analyses, D'Andrade and Shweder appear to have presumed the essential invalidity of personality assessment procedures. However, there exists a large and diverse personality assessment literature attesting to construct-valid connections between assessment measures and the real world that has been overlooked by D'Andrade and Shweder (e.g., Block, 1957; Block, 1971, pp. 159–168, 189–202, 228–238; Block, Jennings, Harvey, & Simpson, 1964; Clausen, 1968; Helson, 1971; Jones, 1968, 1971; Kety, 1974; MacKinnon, 1962; Manheimer & Mellinger, 1967; Peskin, 1973; Robins, 1966; Rosenthal, 1970). A priori, it would appear difficult for a conceptual similarity viewpoint to explain the existence of relationships such as these, sampled from literally hundreds that could have been offered.

The Need to Deepen, Clarify, and Substantiate the Meaning of Conceptual Similarity

The conceptual similarity position would replace the assumption that personality parameters (traits, dispositions) importantly

underlie personality ratings with a linguistic explanation. Leaving aside the empirical relationships that the conceptual similarity interpretation must attempt to encompass, we note that this proffered explanation does not resolve the problem of understanding; it merely transfers or translates the problem. We must still face up to the thorny question of the nature and basis of similarity judgments. The study of similarity is a profoundly complex area of conceptual and empirical inquiry (Tversky, 1977); the invocation of "conceptual similarity" as an explanation without immediate close consideration and articulation of the processes by which similarity judgments are made is not especially helpful. D'Andrade was circumspect in his final claims, acknowledging that because of obscurities surrounding the way in which similarities are developed and recognized,

> It is somewhat ironic that the problem of not knowing what is happening when people are used as measuring instruments, . . . given as the reason why [personality or interactional ratings] produce invalid results, returns to plague [his] formulation about exactly how these invalid results come about. (1974, p. 180)

Shweder was less cautious in his view. He argued that judges make similarity judgments based on the degree to which contiguous attitudes go together in making up what he called a behavioral type, which he treated as a learned cultural construct. Shweder went on vigorously:

> What is disputed is that the *categories* (in our terms, personality characteristics) into which people sort themselves or others can be induced from experience. Cultural *constructs* are not empirical generalizations. (Shweder, 1977b, p. 938)

It would be useful to see the argument and empiricism in support of this strong but undetailed position. Our own view is that although cultural constructs need not be evolved from living in the world, they very often are. Individuals frequently independently generate convergent terms to express their recognition about the people they encounter. To the extent that language is an efficient means of communicating calibrated understandings, individuals will or can come to agree in their usage of terms to describe or integrate or summarize the implications of the behavior of other people (cf. Norman & Goldberg, 1966). The developmental sequence by which children evolve understandings of other people has received some study (Peevers & Secord, 1973) and appears to express the *pragmatic* relevance that descriptions of others in terms of personality characteristics take on for individuals as they interact with the people in their world. Such individually evolved and yet consensual structurings of interpersonal experience provide the basis, we suggest, for many learned cultural constructs. Indeed, with respect to certain personality characteristics or constellations rooted in the common human biology, very different cultures may evolve essentially equivalent cultural constructs encompassing various forms of psychopathology. In a splendid essay, Murphy (1976) brought together evidence from many and diverse societies, primitive and advanced, testifying to a larger consensuality in the cultural constructs of psychopathology that societies separately have experientially educed and codified.

Finally, we note that although the effects attributable to manipulation of the redundancy and structure of the variables being rated are large, the range of correlations between an individual's Conceptual Similarity matrix and the Rated Behavior matrix is interestingly wide. Moreover, the phenomenon previously noted (Block, 1977b) was again observed: A judge's degree of consensuality in conceptual similarity judging, even for the Approximately Orthogonal set, was related to his ability to "retrieve" the Approximately Orthogonal Rated Behavior matrix ($r = .46$, $p < .06$).

Separately, we will be studying the possible implications of these individual differences. There are preliminary indications that these differences are reliable and can provide additional perspective on the processes involved in the effort to develop, conceptualize, integrate, and apply one's psychological understanding of people. Meanwhile, we suggest that the inherent intricacy characterizing both human judgment and the ongoing stream of interpersonal behavior makes it unlikely that so simple a principle as conceptual simi-

larity will provide an appreciable explanation of so complex a process as personality assessment.

Postscript

1. If personality ratings demonstrate conceptually expected concurrent and predictive validity, the semantic "retrieval" of their intercorrelations by Shweder and D'Andrade (1979) takes on a very different implication and significance. We cited a sampling of evidence, from a variety of sources, that ratings can generate replicable external relationships that support their empirical validity. Shweder and D'Andrade state that evidence of empirical validity is "beside the point" (p. 1079) in evaluating the question of the presence or absence of conceptual factors in judges; we do not think so.

2. Interested readers will simply have to judge for themselves, by referring to the original sources, whether the behavior categories worded differently from the rating dimensions "still maintain equivalent meaning," (p. 1078) as Shweder and D'Andrade declare.

3. Because we are without the space for proper psychometric explanation, we can only reiterate that the studies reported by Shweder and D'Andrade "provide no (or technically unsound) reliability coefficients."

4. Shweder and D'Andrade remain impressed by the generality of their finding that appreciable intermatrix correspondence between what they called "actual behaviors" and "rated behaviors" is not observed. We suggest that *the common effect of the many problems besetting their analyses is to increase unreliability and invalidity of measurement and thus to attenuate the possibility of finding strong congruence between Actual Behavior and Rated Behavior matrices*. We agree with Shweder and D'Andrade (1979) that "it is the consistency with which a given result is obtained across variations in method that ultimately supports or disconfirms a hypothesis" (p. 1080). But "the given result" must be a *positive* result, not repeated failures to reject the null hypothesis. The motivated reader should look again at our catalogue of the problems surrounding the comparison of Actual Behavior and Rated Behavior matrices before deciding whether the generally poor intermatrix correspondences observed by Shweder and D'Andrade are deserving of substantive interpretation or are more simply understandable as due to comparing the noncomparable.

5. In our study, we argued that "retrieval" of the matrix of correlations among Rated Behaviors by a matrix of relations among Conceptual Similarity judgments was a function of the particular mix of personality variables employed, namely, their bipolar psychological redundancy. Shweder and D'Andrade (1979) suggest that our reduction of the variance of the distribution of the intervariable correlations creates an "artifactual effect" (p. 1077). But, equally, the high intermatrix correlations previously reported by Shweder and D'Andrade can be viewed as an

"artifactual effect" of extended variances of the distribution of intervariable correlations. Properly, arguments should not arise about artifactual effects on intermatrix congruences; the interdependent intervariable correlations from which they are computed have no "natural" population to which they can be referred so that one can sensibly talk of artificiality or representativeness of their distribution. What is important is that *we have been able to provide a psychological explanation, in terms of redundancy and the proper measurement goals of investigators, of how these different extremes of "artificiality" come about and have their effect.* In particular, high redundancy, both antonymic and synonymic, often has been deliberately introduced by investigators for good reasons (to balance direction of wording effects, to achieve psychometric respectability of subsequent composite scores, etc.). To make such redundancy subtle or indirect would be confusing to the psychologists using these rating scales. It is therefore not surprising that conceptual similarity judges are able to latch onto the structure underlying cleanly separated clusters of variables when highly and simply organized variable sets are employed. But such congruences are essentially adventitious; they have no implications, in and of themselves, for the validity and usefulness of well-based and well-encoded personality ratings.

Accurate Reflection or Systematic Distortion? A Reply to Block, Weiss, and Thorne

Richard A. Shweder
Committee on Human Development
University of Chicago

Roy G. D'Andrade
Department of Anthropology
University of California, San Diego

The "systematic distortion" hypothesis, advocated by D'Andrade and Shweder, states that correlational structures derived from memory-based personality ratings are primarily a product of the conceptual affiliations among rating categories rather than a reflection of the empirical correlational structure of behavior. This hypothesis is clarified with reference to the Block, Weiss, and Thorne critique. The "bipolar redundancy" effect, presented by Block, Weiss, and Thorne as an alternative explanation for correspondence between the correlations derived from memory-based ratings and judgments of conceptual affiliation, is found to be an artifact of reduced variance in matrices of uncorrelated traits. Block, Weiss, and Thorne argue that D'Andrade and Shweder failed to find correspondences between correlations for memory-based ratings and immediate scorings because of methodological flaws in their studies. This argument is reviewed, and it is concluded that the systematic distortion hypothesis remains well supported and that the evidence for the existence of covarying, multibehavior personality traits established by the correlational analysis of memory-based ratings remains dubious. Finally, an attempt is made to clarify the different uses of the term *trait* and to identify the different types of consistency in behavior that are relevant to the controversy.

Most classifications of individual differences in the personality literature are classifications of response patterns on personality rating forms, inventories, and questionnaire interviews. The pattern of correlations among variables in most of these classifications can be reproduced or replicated by asking a small number of respondents to judge the conceptual similarity or dissimilarity of the variables on the rating form, inventory, or questionnaire. To date, results from the following analyses of rating data have been successfully reproduced:

1. Factor-analytic classification of personality adjectives, as given in Norman (1963). (See D'Andrade, 1965; Mulaik, 1964.)

2. Leary grid organization of interpersonal behavior, as given in LaForge and Suzcek (1955). (See D'Andrade, 1965.)

3. Factor-analytic classification of personality and interpersonal behavior, as given in Bales (1970). (See Shweder, 1972, 1975.)

4. Factor-analytic classification of maternal personality, as given in Sears, Maccoby, and Levin (1957). (See Shweder, 1975.)

5. Correlation matrices for Bales Interaction Process Analysis categories used as rating scales, as given in Borgatta, Cottrell, and Mann (1958) and in Mann (1959). (See D'Andrade, 1974.)

6. Partial correlation matrix for observers' ratings of extraversion–introversion in boys in summer camp, as given in Newcomb (1929). (See Shweder, 1975, 1977a.)

7. The Alpha factor from the MMPI, as given in Block (1965). (See Shweder, 1977a, 1977b.)

8. The common factor structure of the

Murray Needs from five personality tests, as given in Fiske (1973) and in Huba and Hamilton (1976). (See Ebbesen & Allen, Note 1.)

9. Syndrome clusters from the Brief Psychiatric Rating Scales, as given in Overall, Hollister, and Pichot (1967). (See Shweder & D'Andrade, Note 2.)

In these studies a variety of techniques for obtaining similarity judgments have been used, ranging from pile sorting to triads testing. The phrasing of the instructions for these judgments has also varied from an emphasis on "co-occurrence" to an emphasis on "likeness in meaning." Similarity judgments appear to be robust, in that small differences in technique do not seem to affect the correspondence found between conceptual similarity judgments and memory-based personality ratings.

At least two hypotheses can be constructed to account for the fact that conceptual similarity judgments reproduce the correlational structure of variables in personality ratings. The first is the "accurate reflection" hypothesis, which asserts that ordinary folk learn or develop "implicit personality theories" that summarize and preserve the empirical covariation of behavior across individual differences in conduct. According to this hypothesis, people use empirically valid implicit personality theories in making conceptual similarity judgments, thereby accurately reporting the intercorrelation of behaviors (Jackson, Chan, & Stricker, in press; Passini & Norman, 1966).

The second hypothesis is the "systematic distortion" hypothesis, which asserts that the correspondence between preexisting ideas of what is like what and memory-based rating correlations occurs because, under difficult memory conditions, people infer what happened from their general model of what the world is like, and because conceptually affiliated memory items are easier to retrieve (Mandler, 1970). According to the systematic distortion hypothesis, the schemata held by most people tend to be inaccurate with respect to how behaviors covary, confusing "what is like what" with "what goes with what." Hence, memory for events contains a systematic bias, in that things that are conceptually similar are recalled as if they covaried. L. J. Chapman (1967) has called this effect "illusory correlation."

A test of the accurate reflection hypothesis versus the systematic distortion hypothesis can be made by obtaining both observational evidence and memory-based ratings for a set of behavioral variables. By observational evidence we mean reasonably objective records made at the time of observation. Such records are called here "immediate scorings." (Block, Weiss, and Thorne, 1979, refer to this type of data as "Actual Behavior matrices.") To the extent that the correlations among variables derived from memory-based ratings are not like the correlations among variables derived from immediate scorings, but are like the pattern of conceptual similarity judgments, the accurate reflection hypothesis is disconfirmed, and the systematic distortion hypothesis supported. (See Shweder, 1977c, Note 3, for other ways to test the accurate reflection and systematic distortion hypotheses.)

In previous papers (D'Andrade, 1973, 1974; Shweder, 1975, 1977a) we examined published sets of data in which immediate scorings and memory-based ratings for the same variables were available. In all cases the pattern of intercorrelations for memory-based ratings was like the pattern of conceptual similarity judgments but only weakly related to the pattern of intercorrelations for the immediate scorings. The evidence supported the systematic distortion hypothesis, and we concluded that personality classifications derived from memory-based data could not be trusted.

Block, Weiss, and Thorne (1979) assert that the systematic distortion hypothesis is not adequately supported. Two general arguments are advanced: the "bipolar redundancy" argument and a series of methodological criticisms.

The Bipolar Redundancy Argument

Block, Weiss, and Thorne (1979) claim that the correspondence between conceptual similarity matrices and correlation matrices for memory-based ratings is "a previously unrecognized function of the high redundancy and

the structure of that redundancy that just happened to be present in the particular variable sets D'Andrade and Shweder sampled" (pp. 1065–1066). They attempt to show this by demonstrating that by varying the degree of bipolar redundancy among variables, they can affect the degree of correspondence between conceptual similarity matrices and correlation matrices for memory-based behavior ratings. Using the California *Q*-set variables and a factor analysis based on ratings by clinical psychologists of a sample of 160 subjects, they selected three sets of 12 items each. For the first set, 6 items with high positive loadings and 6 items with high negative loadings from a single factor were selected; for the second set, 2 items with high positive loadings and 2 items with high negative loadings from three orthogonal factors were selected; for the third set, single items with high loadings from each of 12 approximately orthogonal factors were selected.

For each of these three sets, conceptual similarity judgments were made by a small sample of respondents. For the first set, the mean correlation between the individual conceptual similarity matrices and the rated behavior matrix was found to be .63. For the second set, the mean correlation was found to be .50. But for the third set, which is made up of items from orthogonal factors, the correlation was found to be only .21.

Based on the fact that the mean intermatrix correlation for the orthogonal items is significantly less than the mean intermatrix correlations for items selected from bipolar factors, Block, Weiss, and Thorne (1979) conclude that "Conceptual Similarity – Rated Behavior intermatrix correspondence is high when bipolar redundancy is high and is low when bipolar redundancy is low" (p. 1068) and that they have therefore controlled the degree of correspondence between conceptual similarity and memory-based rating correlations by varying the degree of bipolar redundancy.

We believe that Block, Weiss, and Thorne are incorrect in this claim, since the artifactual effect of the reduced variance within the matrix of orthogonal items has been overlooked. Using Block, Weiss, and Thorne's original data, kindly supplied to us by the authors, and comparing the three data sets, we found standard deviations of .53 and .37 in the rated behavior correlation matrices for the first and second sets, in contrast to a standard deviation of only .15 for the third set. The variability of the rated behavior correlations in the third set has been much reduced by the selection process, and this in turn has reduced the possible covariance between the matrices.

It is also crucial to note that contrary to Block, Weiss, and Thorne's claim, *respondent judgments about the conceptual similarity of the items in the third set do in fact correspond to the level of the correlations in the rated behavior matrix.* Our reanalysis of Block, Weiss, and Thorne's data reveals that the mean conceptual similarity score for items in the third set is 4.3 on a scale for which 1 is defined as "extremely dissimilar," 4 as "unrelated," and 7 as "extremely similar." The mean of the correlations in the rated behavior matrix is .12 disregarding sign. Thus, in a set of almost orthogonal items, conceptual similarity judgments indicate that the items are almost unrelated.

The problem with using correlations to measure the relation between matrices in this instance can be illustrated by considering the extreme case in which all the items are correlated .00 with each other, and all the conceptual similarity judgments are at 4.0, indicating that the items are unrelated. Using correlations as the only measure of correspondence, one would assume that there was no relation between these matrices, even though the judgments and the correlations match perfectly. We conclude that the correspondence between conceptual similarity matrices and correlation matrices for memory-based ratings is not a function of adventitious redundancy.

There is an important methodological problem with the redundancy hypothesis, namely, that the independent variable is operationally the same as one of the dependent variables. By "redundancy" Block, Weiss, and Thorne mean the "communal variance" shared by a set of variables. But communal variance is a function of the intercorrelations between the variables. Therefore, in trying to control for redundancy, they are in effect controlling for

the intercorrelations between variables, which is also one part of the relation they are trying to predict. As a result, in reducing redundancy they necessarily reduce the variance in the intercorrelations between the ratings and, thereby, the possible covariance between matrices.

It is interesting that the redundancy hypothesis asserts part of what the systematic distortion hypothesis asserts: that there is a correspondence between conceptual similarity judgments and the intercorrelations among memory-based behavior ratings (since redundancy is a function of the intercorrelation among variables); however, it reverses the direction of causation and thus becomes a version of the accurate reflection hypothesis.

The Methodological Critique

Block, Weiss, and Thorne (1979) present a series of methodological criticisms concerning the analyses by D'Andrade (1974) and Shweder (1975) of data taken from studies by Newcomb (1929), Borgatta et al. (1958), and Mann (1959). What follows is a list of responses to these criticisms.

1. "The categories or items or dimensions of behavior measured by the Actual Behavior indices are often different from those rated by observers" (Block, Weiss, & Thorne, 1979, p. 1060). This is an important point, since the data were analyzed as if they were from a memory experiment in which the task is to try to remember the relative frequencies of various behaviors across different actors. To the extent that the memory-based ratings were made on categories not equivalent in meaning to the categories used in the immediate scorings, lack of correspondence between the two sets of data becomes artifactual.

Since our analyses were carried out on already-published data, we had no control over how the labeling was done. In our judgment, the categories that do not have identical wording still maintain equivalent meaning. However, it is possible to make a more stringent test by using only categories that have identical wording. We have recomputed the intermatrix correlations for the Mann data using only items that are identically phrased (Categories 2, 3, 4, and 7). The intermatrix correlations between the immediately scored
havior matrices and memory-based rat
matrices for the Mann data are .15, −
−.27, and .03, respectively ($M = -.03$), w
the nonidentical items removed, compared
intermatrix correlations of .07, .20, −.03, a
.27, respectively ($M = .13$), for the data
originally given. Thus removing the items t
were not identically phrased did not incre
(in fact decreased slightly) the corresp
dence between the actual behavior and
memory-based rated behavior matrices.

Since the issue about maintaining equivale
definitions in both conditions is important
evaluating the evidence for or against t
systematic distortion hypothesis, it should
mentioned that relevant data exist in an u
published study (Shweder & D'Andrade, No
2). Block, Weiss, and Thorne did not ha
the results of this study available to them
the time they wrote their critique, nor do t
results of this new study diminish the pert
nence of their concern about this issue. Briefl
this study is similar in design to the studi
already reviewed, except that (a) the cat
gories of behavior were taken from natur
language terms for social interaction (e.g
"advises," "criticizes," etc.), (b) the immed
ate scoring categories and the memory-base
rating categories are identical, and (c) th
stimulus material consisted of videotape
natural family interaction, thereby permittin
immediate scoring by a number of observer
The intermatrix correlations are quite simil
to the results found in the other cases: Th
correlation between the immediately score
behavior matrix and the memory-based be
havior rating matrix is .23; the correlatio
between the memory-based behavior ratin
matrix and the conceptual similarity matri
is .75; and the correlation between the im
mediately scored behavior matrix and the con
ceptual similarity matrix is .00.

In summary, on the basis of the recompute
figures and the new study, we conclude tha
the low degree of correspondence we hav
consistently found between memory-base
rated behavior correlation matrices and im
mediately scored behavior correlation matrice
is not a product of wording changes in be
havioral categories.

2. "Emphasis solely on the correlations between traits ignores consideration of the validity of specific traits" (Block, Weiss, & Thorne, 1979, p. 1061). This is true, but beside the point. The reason for the emphasis on the correlations between traits is that it is these correlations that test the systematic distortion and accurate reflection hypotheses. Of course, if the correspondence between the memory-based data and the immediately scored data were very high, there would not be enough error variance for systematic distortion to take place. However, the correlations between specific immediate scorings and memory-based behavior ratings are in the .3 range. Even rigorous correction for attenuation would not put the level of validity so high that there would be insufficient error variance to permit the effect of systematic distortion to occur.

Related to the issue of validity, Block, Weiss, and Thorne (1979) raise questions about the reliability of the immediate scorings. They assert that "because the three studies provide no (or technically unsound) reliability coefficients, we cannot estimate what the relationships between the Rated Behavior and the Actual Behavior variables would be if they were psychometrically improved" (p. 1062). For the Newcomb (1929) study, an odd–even day reliability check on behavior percentages yielded a mean reliability coefficient of .78 over 26 variables. In the Borgatta et al. (1958) study, reliability was based on comparing the profiles of the three groups across two sessions, with the results presented graphically. From visual inspection there appears to be high consistency in the results for each group across sessions. In the Mann (1959) study, Mann did the scoring alone. However, he had worked with R. F. Bales for 3 years and had attained a scoring reliability of approximately .90 on the majority of the categories, with Bales as the criterion. However, since the reliabilities are not given on a category-by-category basis, Block, Weiss, and Thorne are correct in pointing out that correction for attenuation cannot be made. Nevertheless, the figures indicate that the immediate scorings have reasonable mean reliability in all three studies.

3. "The use of frequency counts of behavior is not a sufficient means of operationalizing complex psychological concepts" (Block, Weiss, & Thorne, 1979, p. 1062). Again, this is true but beside the point. This criticism would be appropriate were we trying to develop a personality assessment instrument. Our main concern in these studies is not to develop personality assessment techniques but to test hypotheses about systematic distortion in memory. In trying to anchor one set of ratings in what can be observed and counted, we have used studies that used relatively simple and direct methods. If we did not have simple and direct measures, how could we know whether memory distortion had occurred?

This same general point holds for the related criticism by Block, Weiss, and Thorne that the categories of Interaction Process Analysis (IPA) are not the most effective means of describing social interaction and (on the other side of the fence) the criticism that the Newcomb categories require considerable psychological inference. Difficulties in applying particular category systems would be likely to lower the validity of the ratings, but would not introduce systematic distortion.

Block, Weiss, and Thorne (1979) also question the use of averages as a way of summarizing behavior. They say, "Useful though the averaging basis underlying the 'actual behavior' scores may generally be, such scores may not be able to capture important information and recognitions codable by raters who use long-term memory" (p. 1064). We do not deny these criticisms of averages, but we do deny the relevance of these criticisms to our research. Repeating the point made above, such criticisms would apply if we were attempting to assess the personality of the subjects rated in these studies. Given that we are trying to test hypotheses about memory, we hold that these criticisms do not apply, since the methods used did not artifactually introduce systematic distortion. Were it the case that the memory-based raters captured important information not to be found in the immediate scorings, this would affect the correlations between specific categories across conditions but would not affect the relation between the correlation matrices.

4. "Extraneous influences distorting correlation coefficients and their patterning are not considered" (Block, Weiss, & Thorne, 1979, p. 1064). First, Block, Weiss, and Thorne make the point that the IPA rates are likely to be highly skewed or not unimodal, which will tend to lower correlations. Second, where the behavior counts are transformed into percentages, some degree of negativity is introduced into the correlation matrix. Third, in four of the five sets of data, the memory-based behavior rating data were based on pooled judgments from a number of observers, but the immediately scored behavior data were obtained from a single observer, so that the discrepancies may be a function of the "volatility" of the immediate scorings.

If we had merely presented one test of the systematic distortion hypothesis that had all of these problems, our results would be equivocal. However, we have presented a number of different tests of the systematic distortion hypothesis on different types of data, collected by different investigators, using different methods. One advantage of using a number of different tests is that criticisms of the data or of the procedures in one case can be matched with a case in which the criticism does not apply. We can then see if the same results obtain. Thus the Newcomb (1929) data do not have distributional difficulties of the sort that might have affected the Mann (1959) data, and these data are also not affected by the negativity problem. Further, in the Mann study there are two sets of data—one in which there is no discrepancy between the number of subjects used in the memory-based behavior rating condition and the number of subjects used in the immediately scored behavior condition, and one in which there is. No difference is observed in the results. Thus, to each of Block, Weiss, and Thorne's three criticisms there are one or more tests to which the criticism does not apply, yet the same pattern of findings occurs. Almost every study has some methodological weak point. We believe it is the consistency with which a given result is obtained across variations in method that ultimately supports or disconfirms a hypothesis.

Also included under the heading of "extraneous influences" by Block, Weiss, a Thorne are two other criticisms. The fi concerns the use of correlations to measu the degree of relatedness between two matric of correlations. Block, Weiss, and Thor point out that because of the lack of ind pendence in the "observations," the norm interpretations of the correlation coefficie with regard to amount of variance explain and levels of significance are inappropria To date we have not found a better way compare these types of correlation matrice However, even under these conditions, the co relation coefficient maintains its descripti value, yielding an interpretable figure, whi indicates how well one can predict from o to the other set of measurements. Since have no alternative, and since we are primari interested in obtaining a comparative figu for the *relative* degree of association betwe various sets of measurements, we have pe force relied on the product-moment a Spearman's rank-order correlation coefficie

The second issue concerns the effect of flecting variables in a matrix of correlatio thereby changing the degree of association b tween matrices. Since some psychological va ables permit such reflections, it is possib that some of the variables could have be reflected, which would possibly have chang the relationship between matrices. Howeve this criticism applies only to some of the stu ies that attempt to reproduce the structur found in various personality assessment i struments. None of the variables we have us in comparing immediately scored behavi matrices with memory-based behavior rati matrices were of the dimensional or bipol types that would permit reflection, and this particular problem does not affect our a tempts to test the systematic distortion h pothesis.

Last on the list of methodological criticism Block, Weiss, and Thorne (1979) raise t question of whether the correlations fou between the immediately scored behavior m trices and memory-based behavior rating m trices are so high that it is impossible to "u confound the conceptual similarity interpret tion from the isomorphism view" (p. 1065 They say, "Instead of being impressed th

these 'coefficients' are so low, one can as well be surprised that they are so high" (p. 1065). However, the test of the systematic distortion versus accurate reflection hypothesis requires the comparison of *three* correlations: (a) the correlation between the memory-based behavior rating matrix and the conceptual similarity matrix, (b) the correlation between the memory-based behavior rating matrix and the immediately scored behavior matrix, and (c) the correlation between the immediately scored behavior matrix and the conceptual similarity matrix.

Across seven different tests we find the following: (a) The mean correlation between memory-based behavior rating matrices and immediately scored behavior matrices is .25; (b) the mean correlation between memory-based behavior rating matrices and conceptual similarity matrices is .75; and (c) the mean correlation between the immediately scored behavior matrices and conceptual similarity matrices is .26.

Comparing the three relationships, we observe that the relation between the matrices for memory-based ratings and the matrices for immediate scorings is weaker than the relation between the matrices for memory-based ratings and the conceptual similarity matrices. This result is not due to some effect of the relation between the immediate scoring matrices and the conceptual similarity matrices, since these are also only weakly related. It is this pattern of correlations that supports the systematic distortion hypothesis, not our impression of whether any one of these relationships is surprisingly strong or weak.

Theoretical Issues

In the final section of their article, Block, Weiss, and Thorne take up a series of general theoretical issues concerning the conceptual similarity position. One of the issues they raise concerns the nature and the basis of similarity judgments. "The study of similarity is a profoundly complex area of conceptual and empirical inquiry (Tversky, 1977); the invocation of 'conceptual similarity' as an explanation without immediate close consideration and articulation of the processes by which similarity judgments are made is not especially helpful" (Block, Weiss, & Thorne, 1979, p. 1071). The study of similarity judgments has been a neglected area. A simple model, informally presented, dealing with only the denotative aspects of meaning, is given in Romney and D'Andrade (1964). It is our current view that similarity judgments are based on the relative number of predications common to the two terms being rated; such predications we believe refer to a wide variety of things, including the sets to which both items belong, parts which are common to both items, common effects of both items, and so on. The study of similarity can be divided into two parts: The first is to determine how information is processed in making a judgment; the second is to determine what informational content is being processed. Multidimensional scaling of similarity judgments has proven to be an effective way of investigating the second problem (Romney & D'Andrade, 1964; Shepard, 1974). It seems likely that with the stimulus of Tversky's model there will soon be an increase in research on the first problem.

Another general issue taken up by Block, Weiss, and Thorne (1979) is the degree to which cultural belief systems can be assumed to be veridical. They point out that although constructs need not be empirically accurate, they often are. Further, they argue that there is good reason to expect cultures and individuals to develop both reliable and valid ways of describing human personality (p. 1071).

As anthropologists interested in the relation between culture and cognition, we support the generalization that cultural belief systems are sometimes empirically accurate. However, having some experience with the strong commitment people often have to beliefs that are empirically inaccurate, we feel that the other side of the proposition also needs stating; that is, cultural belief systems can be quite inaccurate and yet quite compelling. In this instance, the question is whether people have personality traits consisting of covarying behaviors. The fact that this is believed to be true in our culture does not constitute evidence for either its truth or its falsity.

From a more psychologically oriented per-

spective, Block, Weiss, and Thorne (1979) assert: "In seeking to dispense with personality ratings and personality inventories on the basis of their conceptual similarity arguments and analyses, D'Andrade and Shweder appear to have presumed the essential invalidity of personality assessment procedures" (p. 1070). Arguing for the essential validity of personality assessment procedures, Block, Weiss, and Thorne introduce "some relationships of a kind that personality psychologists find reinforcing of their belief in reliable individual differences with regard to personality parameters of consequence in the real world" (p. 1069). As examples of relationships of this kind they point to across-time consistencies in trait ratings and the ability of personality assessment measures to discriminate between criterion groups. Such relationships, they assert, can be neither reproduced nor explained by the conceptual similarity position.

It is true that such relationships, to the extent they did exist, could not be reproduced or explained by reference to conceptual similarity. This is because the conceptual similarity argument has no bearing on the issue of perceived longitudinal consistency or on the asserted ability of personality measures to discriminate between criterion groups.

What becomes apparent in examining the final section of Block, Weiss, and Thorne's article is that there are (at least) two uses of the term *trait* and the related phrase *individual differences*. The conceptual similarity position is part of an attack on the hypothesis that people have global traits and on the related hypothesis that one can determine such traits through the analysis of individual differences. The defense given by Block, Weiss, and Thorne concerns the predictive utility of traits—but in a different sense of the word—and the possibility of determining such traits through the analysis of individual differences—in a different sense of the phrase.

Originally, the notion of a trait appears to have contained four distinct kinds of consistency: consisting across similar behaviors (an honest person does not lie, does not steal, and does not cheat); consistency across situations (an honest person does not cheat when taking a math test and does not cheat when playing a ring toss game); consistency across time (an honest person is likely to have been honest yesterday and will be honest tomorrow); and consistency within a framework of psychological functioning (honesty is theoretically and empirically related to self-control and identification with parental figures). (See McClelland, 1951, 210–234.)

The kind of trait consistency that is relevant to the conceptual similarity position is consistency across similar behaviors. The classical approach to the problem of determining consistency across similar behaviors is correlational analysis, in which the correlations are computed across persons, as typified by the work of Eysenck and Cattell. This approach assumes that individual differences arise from differences between persons in the amount of a trait, and so the co-variation of behaviors across persons can be used to determine which behaviors belong to which traits (Cattell, 1946).

It has been our position that evidence for the existence of this type of trait—this type of consistency across similar behaviors—is rather dubious. Most of the supporting data are from memory-based ratings, questionnaires, and inventories. (Correlational data from self-report tests can be considered "objective evidence" in one sense, but such data do not establish that the behaviors reported on actually co-occur as rated.) We believe that memory-based data are so strongly affected by conceptually based systematic distortion that they are primarily evidence for the existence of a powerful cultural belief system.

However, the definition of *trait* given above does not correspond to the use of the term by Block, Weiss, and Thorne (1979). They say:

> Personality psychologists seek or settle on useful sets of variables to be employed for the specification of the personal or behavioral qualities of the individuals to be studied. To the extent that the set of personality or behavioral variables has communal variance (i.e., is redundant), there will be a "similarity structure of the trait measurements." But such similarity structures represent neither conceptual nor empirical fixities. (p. 1056–1057)

Thus, for Block, Weiss, and Thorne, the emphasis is on useful ratings, which usually involve constructing a composite index across

a number of measures. The different measures to be placed in a composite index do not have to be internally correlated or homogeneous; they may even lack face validity, as long as the composite index displays significant relationships with an external criterion.

With respect to current personality assessment work as described by Block, Weiss, and Thorne, it appears that two of the four types of consistency originally contained in the notion of a trait have been dropped or suspended: consistency across similar behaviors and consistency across different situations. If true, this is an interesting shift. We have been arguing that one of these two suspended types of consistency has little empirical warrant, and we are encouraged to believe that this position no longer appears heretical.

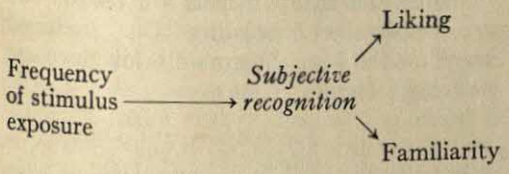
Exposure Effects May Not Depend on Stimulus Recognition

Richard L. Moreland
University of Pittsburgh

Robert B. Zajonc
University of Michigan

Birnbaum and Mellers have presented an alternative theoretical model for Moreland and Zajonc's data on the role of stimulus recognition in the mere exposure phenomenon. They contend that the exposure effects observed in the authors' research could have been produced by a single underlying factor called *subjective recognition*. Birnbaum and Mellers' model is quite plausible, and follows the traditional view that the improvement in attitudes associated with repeated stimulus exposure arises largely from increasing stimulus familiarity. In order to investigate how well their one-factor model, as well as the authors' own two-factor model, actually fits the data, a series of linear structural equation analyses was carried out. The results revealed that the two-factor model provided a significantly better degree of fit. Moreland and Zajonc's original conclusions thus received additional support—stimulus recognition still does not appear to be a necessary condition for the occurrence of exposure effects.

Recently, we reported on the results of two experiments that sought to determine whether stimulus recognition was a necessary condition for the occurrence of exposure effects (Moreland & Zajonc, 1977). Our analyses of the data from those two experiments suggested that it was not. Birnbaum and Mellers (1979b), however, have since offered an alternative model for our data. Their model takes the following form,



in which familiarity and liking ratings are viewed as imperfect measures (with uncorrelated errors) of "subjective recognition"—a hypothetical mediating factor that depends on the frequency of stimulus exposure.

Birnbaum and Mellers evaluated their model by examining the pattern of correlations among the three major variables (frequency of stimulus exposure, liking, and subjective familiarity) in each of our experiments. In both cases, the correlations were consistent with a one-factor model of the data. Birnbaum and Mellers concluded, therefore, that stimulus recognition may have indeed mediated the observed exposure effects.

This new theoretical model provides a plausible explanation for our results. There are at least two important issues that must be considered, however, before any final conclusions can be drawn about the role of stimulus recognition in producing exposure effects. The first of those issues involves the nature of the proposed mediating factor. Birnbaum and Mellers (1979b) showed that a one-factor model was consistent with our data, and in accordance with the null hypothesis being tested, they called that factor "subjective recognition." It should be noted, however, that the true nature of such a factor remains an open issue. All that Birnbaum and Mellers really showed was that *some* single factor *could* have had an impact on our results. They

This research was supported by National Science Foundation Grant GS-35495. The authors would like to thank Frank Andrews, David Kenny, Laura Klem, and Henry Law for their advice on statistical issues, and Mary Grace Moore for her help with the data analyses.

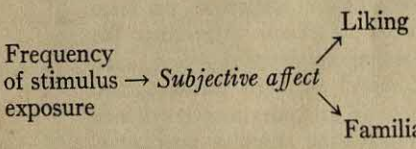
did not prove, nor did they claim to prove, that those results were in fact influenced by stimulus recognition. It could be argued, for example, that the exposure effects observed in our experiments were actually mediated by feelings of "subjective affect," as indicated in the model shown below:



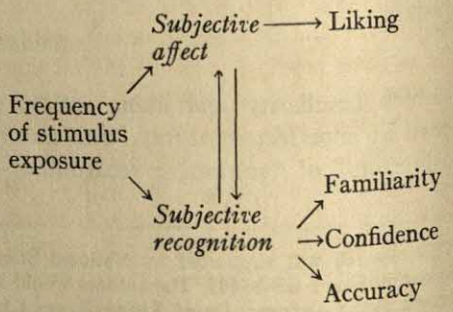
This affective model, which we described briefly in our earlier article, does not require any conscious form of stimulus recognition for the occurrence of exposure effects. Nevertheless, it is a model that Birnbaum and Mellers would have to accept as a possible explanation for our results, since it is in complete accordance with their own analyses of the data. A valid decision regarding the nature of their hypothetical mediating factor cannot be made on the basis of the available evidence. In particular, these is no good empirical reason to believe that the exposure effects observed in our two experiments were mediated by stimulus recognition.

A second important issue, quite distinct from the first, involves the ability of *any* one-factor model to account for our results. Birnbaum and Mellers showed that their own model was at least consistent with our data. That does not mean, however, that their model must necessarily be accepted as the best explanation for our results, or that more complex theoretical models must now be rejected on any grounds other than parsimony. Clearly, it would be both interesting and informative to specify several potential models of exposure effects and then investigate the degree to which each of them actually fits the observed data.

In order to examine our data more closely, we decided to perform some linear structural equation analyses. Unlike sociologists, econometricians, and political scientists, relatively few experimental social psychologists have taken advantage of these powerful analytical techniques, which can be used to evaluate a variety of fairly complex causal models within a single data set (cf. Jöreskog & Sörbom, 1977; Long, 1976). We used the LISREL III program (Jöreskog & Sörbom, 1976) to calculate maximum likelihood estimates for several causal models of our data. This program distinguishes between latent variables (constructs) and their observed indicators (measures), and allows the researcher to specify particular causal models for the variables under investigation. By estimating any unknown coefficients in the system of linear structural equations for a particular model, the program reveals the pattern of relations among its latent variables, differentiating causal effects from unexplained variance in each case. An unstandardized maximum likelihood solution, as well as a standardized solution, is generated for each causal model that is specified.

Using the LISREL III program, we were able to evaluate the degree to which several different models fit our data. For the present purposes, we will only describe the results of analyses performed on the data from our second experiment.[1] The program's input for those analyses was the matrix of intercorrelations among five variables: frequency of stimulus exposure, liking, subjective familiarity, recognition confidence, and recognition accuracy. The actual correlations are shown in Table 1.

Among the many models we tested, two were especially interesting. Our preferred model for the data, illustrated below, involved two major factors:



[1] Similar results were found in the data from both experiments. The data from the second experiment were more suitable for LISREL III analyses, however, because (a) more subjects were tested, (b) separate measures of the various recognition variables were obtained, and (c) recognition and liking measures were obtained from the same individuals.

Table 1
Matrix of Intercorrelations for Experiment 2

Variable	1	2	3	4	5
1. Frequency of stimulus exposure	1.00				
2. Liking	.663	1.00			
3. Subjective familiarity	.579	.533	1.00		
4. Recognition confidence	.340	.252	.291	1.00	
5. Recognition accuracy	.413	.302	.555	.417	1.00

Note. Frequency of stimulus exposure is the log plus one of the actual exposure frequency. All of these correlations were calculated using the residual data set (cf. Moreland & Zajonc, 1977, p. 195).

Briefly, we felt that repeated exposure to a novel stimulus could produce feelings of *both* recognition and affect, each of which might in turn have some influence of its own on the other. Liking ratings were assumed to be primarily affective in nature, while responses on the various recognition measures were thought to share a more cognitive origin.

Applying this two-factor model to the data from our second experiment, we obtained the standardized solution shown in Figure 1. Latent variables are shown there in ellipses, while indicators of those variables are shown in boxes. The path coefficients linking ellipses with boxes represent the estimated validities with which the latent variables were measured by their respective predictors. Path coefficients linking latent variables to each other represent the estimated strength of particular causal relationships. Unexplained variance in the latent variables (V_1 and V_2) and measurement error in their indicators (E_1 to E_5) are also estimated. Note that a few of the model's parameters (shown in parentheses) were set equal to some a priori value in the maximum likelihood solution, so that the variance in all of the latent variables could be identified.[2]

The results provided some interesting information about our data. The chain of paths linking stimulus exposure to subjective recognition, and subjective recognition to subjective affect, indicated that some of the exposure effects observed in our research may have indeed been mediated by subjective recognition. However, there was also a relatively strong and direct path linking stimulus exposure to subjective affect, suggesting that subjective recognition was not an essential factor in producing our results. The overall goodness of fit for our model was $\chi^2(5) = 38.99$.[3]

The standardized solution that we obtained when Birnbaum and Mellers' (1979b) one-factor model was applied to the same data set

[2] Since stimulus exposure and subjective affect each had only one indicator, the program could not successfully identify their variance. For that reason, we specified (in the maximum likelihood solution) both the validity and the error coefficients for those two indicators. Frequency of stimulus exposure was assumed to have a validity of 1.00 (and an error of .00), as it represented a presumably perfect experimental manipulation of stimulus exposure. The validity coefficient for liking was set equal to .87 (and its error coefficient to .24) on the basis of a reliability estimate obtained in our original research (cf. Moreland & Zajonc, 1977, pp. 195 and 197). In order for the program to identify the variance in subjective recognition, we followed an accepted standard practice, and set the validity coefficient for subjective familiarity to 1.00, again in the maximum likelihood solution. It should be noted that parameters whose values were specified in the maximum likelihood solution sometimes took on slightly different values in the standardized solution. These differences occurred whenever the estimated variability of a latent variable was less than 1.00, and were a natural by-product of the standardization procedure (cf. Jöreskog & Sörbom, 1976, p. 24).

We also specified that the two path coefficients between subjective affect and subjective recognition had to be equal to each other in the maximum likelihood solution. This was equivalent to specifying the value of a single parameter, and therefore added a single degree of freedom to the chi-square. Without this additional constraint, which is often adopted when testing models involving reciprocal causation (cf. Wiley, 1973; Wright, 1960), our model would have been underidentified.

[3] The degrees of freedom for this chi-square are the number of cells in the correlation matrix (including the diagonals) minus the number of "free" parameters. The chi-square measuring goodness of fit was fairly large for all of the models that we tested. Jöreskog (1969) has suggested, however, that the chi-square statistic may not, in itself, provide the most useful information about how well a model

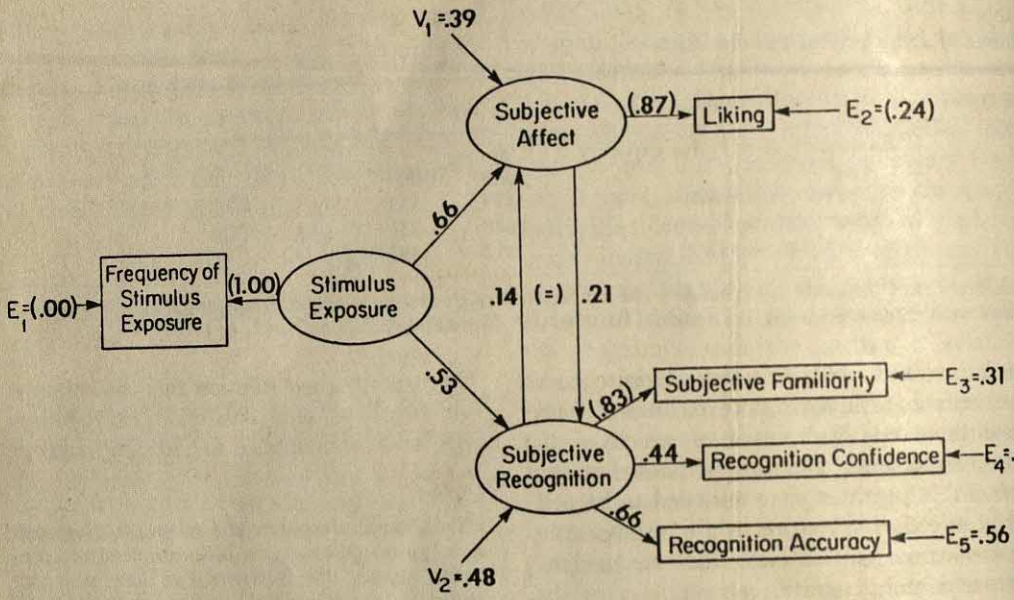


Figure 1. Moreland and Zajonc's two-factor model of exposure effects (standardized solution). (V = variable; E = error.)

is illustrated in Figure 2. The same parameter constraints described earlier were again used. In general, the path coefficients for this model seemed reasonable, although it was somewhat surprising that liking measured subjective recognition as well as subjective familiarity did, and even better than recognition confidence or recognition accuracy were able to do.[4] If our data were indeed influenced by subjective recognition, as Birnbaum and Mellers' model indicates, then variables meant to measure recognition processes should have been most closely associated with that factor. The overall goodness of fit for Birnbaum and Mellers' model was $\chi^2(6) = 83.58$.

To compare the accuracy of these two models, we first took Jöreskog's (1969) suggestion and looked to see which one had the lower ratio between its chi-square and degrees of freedom. According to that criterion, our own model of the data (38.99:5 = 7.80) was clearly better than the one proposed by Birnbaum and Mellers (83.58:6 = 13.93). Since their model was actually nested within ours, however, a statistical test could be made by subtracting the chi-square and degrees of freedom for one model from those of the other (cf. Long, 1976). The results showed that our model provided a significantly better fit to the data, $\chi^2(1) = 44.59$, $p < .01$.

In summary, we see no reason to alter our earlier conclusions about the role of stimulus

fits the data. Instead, he recommends looking at the ratio between the chi-square and its degrees of freedom as another means of evaluating the degree of fit (cf. Jöreskog, 1969, p. 201).

[4] In the accompanying article, Birnbaum and Mellers (1979a) have argued that at least two of the recognition measures (confidence and accuracy) were related to stimulus exposure in a nonlinear manner and thus could not be expected to load more heavily on subjective recognition. In order to test this argument, we repeated the two LISREL III analyses reported here, but allowed for the possibility of correlated errors between recognition confidence and recognition accuracy. This was accomplished by introducing a new latent variable into each analysis, one that was unrelated to any of the other latent variables in the model and was measured only by the confidence and accuracy of the subjects' recognition responses. Both of the revised models fit the data better than their predecessors did, indicating that shared nonlinearity among the recognition measures was indeed a factor in our research. Nevertheless, even after the possibility of correlated errors between recognition confidence and recognition accuracy was taken into account, our own model of the data was still more accurate than that proposed by Birnbaum and Mellers.

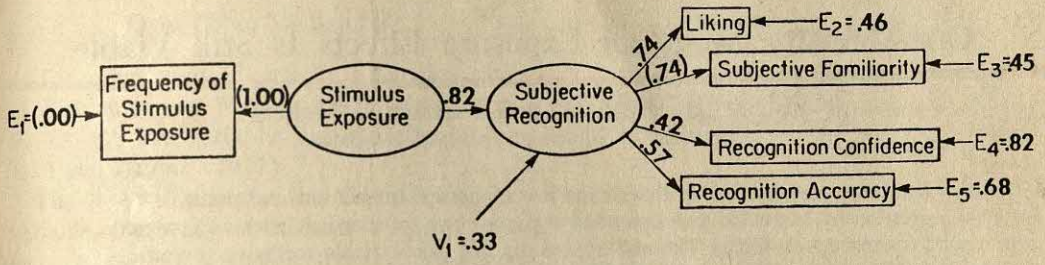

Figure 2. Birnbaum and Mellers' one-factor model of exposure effects (standardized solution). (V = variable; E = error.)

recognition in producing exposure effects. Birnbaum and Mellers (1979b) proved that a one-factor model of our data cannot be rejected. The nature of their hypothetical factor, however, remains a mystery—in particular, there is no evidence to show that it necessarily involved any form of stimulus recognition. Moreover, the fact that a one-factor model (of any sort) was consistent with our data says little about the relative ability of such a model to account for our results. In fact, when we reanalyzed our data using linear structural equation analyses, the results showed that our own two-factor model provided a significantly better fit. This finding, along with the results of other research (cf. Matlin, 1971; Wilson, 1975, 1979), strongly suggests that stimulus recognition is not a necessary condition for the occurrence of exposure effects.

One-Mediator Model of Exposure Effects Is Still Viable

Michael H. Birnbaum and Barbara A. Mellers
University of Illinois at Urbana-Champaign

Birnbaum and Mellers criticized the use of partial correlation and multiple regression by Moreland and Zajonc to argue for two independent effects of stimulus exposure on liking. The null hypothesis that one variable mediates the effect of the independent variable on the dependent variables was not tested by their analyses. In response, Moreland and Zajonc reanalyzed their data, using structural equations analysis, and replied that there is evidence to support their previous conclusions. However, the present article shows that the small residuals from the one-mediator model may be due to shared nonlinearity (correlated errors) in three of the dependent variables. This simpler interpretation achieves a better fit to the Moreland and Zajonc data than the two-mediator model they advocated. Since the null hypothesis of one mediator is still viable, the burden of proof rests on those who contend that there is more to the exposure effect than stimulus recognition.

Moreland and Zajonc (1977) replicated the exposure effect, that is, the finding that stimuli that are presented with greater frequency will be rated more favorably. They also asked their subjects to rate their familiarity with the stimuli, and they found a significant partial correlation between liking and exposure frequency when rated familiarity was partialed out. This partial correlation (and related regression analyses) led them to conclude that there is an additional, "independent" effect of exposure frequency on liking that is not mediated by stimulus recognition.

Birnbaum and Mellers (1979) questioned the use of partial correlation and regression in this argument. They pointed out that the null hypothesis that a single variable (e.g., recognition) mediates the effect of the independent variable on *both* dependent variables predicts that both partials should have the same sign as the original correlations. Only if the dependent variable measuring recognition is assumed to be perfectly correlated with the mediator does the regression analysis test the null hypothesis. Otherwise, lack of perfect validity of the dependent variable vitiates the analysis.

Birnbaum and Mellers (1979) presented path models both for the null hypothesis of one mediator and for the alternative hypothesis that a second mediator is required. Implications of the models and methods to distinguish them were described. These methods were applied to the three major variables in Moreland and Zajonc (1977) with the result that no evidence was found to require the hypothesis of two mediators over the simpler hypothesis of one.

In response to these arguments, Moreland and Zajonc (1979) reanalyzed their data, using structural equations analysis. They argued that when all five variables are considered, a case can be made for the existence of an extra path from stimulus frequency to liking, in addition to the path via subjective recognition. However, the present article will show that the residuals from the one-mediator model, fit to all five variables, are small in magnitude and are not of the form anticipated by the Moreland and Zajonc model. Instead, they can be explained by the simpler hypothesis that some of the dependent variables are nonlinearly related to the single mediator.

One or Two Mediators?

The diagram in Figure 1 is an extension of Birnbaum and Mellers (1979, Expression 9) for all five variables reported by Moreland and Zajonc (1977).

The diagram indicates that the independent variable, frequency of stimulus exposure, affects a mediator, "subjective recognition," which in turn influences the four dependent variables, rated affect (liking), rated familiarity, rated recognition confidence, and recognition accuracy. Moreland and Zajonc (1977, 1979) argue that there is an additional, independent effect of stimulus exposure on liking, presumably via a second mediator, labeled "subjective affect" in Figure 1.

The one-mediator model is a special case of Figure 1 with $b = 0$. The model favored by Moreland and Zajonc (1979, Figure 1), although written in more complex form, is also a special case of Figure 1, with $c_1 = c_2 = c_3 = 0$.

One-Mediator Model

Table 1 shows the residual correlations that remain after fitting a linear one-mediator model ($b = 0$, $c_1 = c_2 = c_3 = 0$) to the correlations for both experiments of Moreland and Zajonc (1977; see Table 1 of Birnbaum & Mellers, 1979). Models were fit to maximum likelihood criterion by means of ACOVS and LISREL III (Jöreskog, 1974; Jöreskog, Gruvaeus, & van Thillo, 1970; Jöreskog & Sörbom, 1976). In general, the residual correlations in Table 1 are small in magnitude. In particular, the largest deviation does not occur for the residual correlation between liking (affect) and frequency (only .03 and .06 for Experiments 1 and 2), which might be expected to be large if there is an extra causal path from frequency to liking. Instead, the largest residual for both experiments is for the correlation between recognition accuracy and recognition confidence (.08 and .18).

One can reasonably ask if the residual correlations in Table 1, which (for Experiment 2) are based on 10 ratings from each of 40 subjects, are of sufficient magnitude to reject the one-mediator model. Moreland and Zajonc (1979) contend that the lack of fit for this

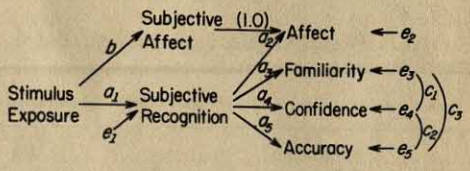

Figure 1. Path diagram representing theories of stimulus exposure. (The coefficient a_1 represents the correlation between stimulus exposure and a mediator, labeled "subjective recognition," which in turn is correlated with the four dependent variables with coefficients of a_2, a_3, a_4, and a_5. The errors, e_1 through e_5 represent residuals, analogous to uniquenesses in factor analysis. The coefficient b represents the effect of stimulus exposure on liking apart from its effect via the first mediator. The correlations c_1, c_2, and c_3 allow for correlated errors, which could be produced by shared nonlinearity of the dependent variables measuring recognition. The issue at hand is whether the data of Moreland and Zajonc (1977) provide sound evidence to reject the null hypothesis that $b = 0$.)

model is evidence of a second mediator. It will be shown below that this pattern of small residual correlations can be better fit by a one-mediator model, which allows the errors in the recognition measures to be correlated (i.e., the cs in Figure 1 are not fixed to zero). Shared nonlinearity of the recognition measures would predict correlated errors.

Nonlinearity in Moreland and Zajonc Data

Figure 2A plots the means of the four dependent variables as a function of the independent variable, log stimulus frequency, as reported in Table 3 of Moreland and Zajonc (1977). The ordinate has been recalibrated linearly so that all four dependent variables can be shown simultaneously. The one-mediator model and the two-mediator model both imply that the curves should all be linear. Should two variables share common nonlinearity, the residual correlation in Table 1 is expected to be positive. All three recognition measures appear to be nonlinearly related to frequency of stimulus exposure. Furthermore, recognition confidence and recognition accuracy appear to share a common cubic trend in relation to the other curves. A similar pattern was evident for Experiment 1. Thus, the two variables that show the largest residual from the one-mediator model (Table

Table 1
Residuals From One-Mediator Linear Model

	Frequency	Liking	Familiarity	Confidence	Accuracy
Frequency		.03	.01	.02	−.07
Affect	.06		−.01	.02	−.06
Familiarity	−.03	−.02		−.06	.04
Confidence	−.01	−.06	−.02		.08
Accuracy	−.05	−.11	.13	.18	

Note. Each entry is the residual correlation after fitting a one-mediator model to the correlations obtained by Moreland and Zajonc (1977). Values above the diagonal are for Experiment 1; values below the diagonal are for Experiment 2. Liking and affect are corresponding measures for Experiments 1 and 2, respectively. The question under consideration is whether correlations of this pattern and magnitude, based on 10 judgments from each of 40 subjects (Experiment 2), warrant rejection of the one-mediator model. Note that the largest residuals involve accuracy, which is nonlinearly related to frequency (Figure 2).

1) are the two that are most nonlinearly related to the others (Figure 2A).

Nonlinearity Can Produce Correlated Residuals

To illustrate how shared nonlinearity can produce deviations from a one-mediator model, a hypothetical data set was constructed from the following one-mediator model:

$$\begin{aligned} F &= X + e_1; \\ Y_1 &= F + e_2; \\ Y_2 &= F + .33F^2 + e_3; \\ Y_3 &= F + .33F^2 + e_4; \\ Y_4 &= F + .33F^2 + e_5; \end{aligned} \qquad (1)$$

where X is the manipulated independent variable (analogous to stimulus exposure in Figure 1); Y_1 through Y_4 are the measured, dependent variables; F is the mediating factor (analogous to subjective recognition); the addition of $.33F^2$ produces nonlinear relationships between Y_2 through Y_4 and F; and e_1 through e_5 are mutually uncorrelated error terms. The value .33 for the coefficient of F^2 was chosen so that the degree of nonlinearity would be roughly comparable to that in the data of Moreland and Zajonc (1977), as in Figure 2A. To generate the 160 hypothetical cases, 5 values of X, (−2, −1, 0, 1, 2) were factorially combined with 2 values of e_1 (−1, 1) to produce 10 values of F. These values of F were factorially combined with two levels of each error ($e_2 = -1.1, 1.1$; $e_3 = -4, 4$; $e_4 = -3, 3$; $e_5 = -2, 2$) to generate the values of the dependent variables, Y_1, Y_2, Y_3, and Y_4, according to Equation 1. The mean values for Y for each level of X are shown in Figure 2B, plotted for comparison with Figure 2A. For the hypothetical example, variables Y_2, Y_3, and Y_4 share a common nonlinear (quadratic) relationship with the other two variables. If the data were generated without the F^2 terms, the curves would be linear; therefore, the linear one-mediator model (with $b = c_1 = c_2 = c_3$ fixed to zero in Figure 1) would fit perfectly.

The correlation matrix, generated from the

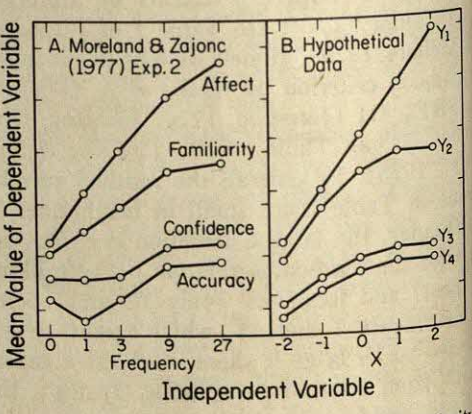

Figure 2. A. Mean values of affect, rated familiarity, recognition confidence, and recognition accuracy as a function of exposure frequency [log (f + 1)]. (From Moreland & Zajonc, 1977, Table 3. Ordinate separately calibrated for each variable.) B. Mean values of dependent variables, Y_1, Y_2, Y_3, and Y_4, as a function of independent variable. (Hypothetical data were generated from a one-mediator model with Y_2, Y_3, and Y_4 nonlinearly related to the mediating variable, as shown in Equation 1.)

one-mediator model of Equation 1 (with some dependent variables nonlinearly related to the mediator), is shown in the upper portion of Table 2. The correlation matrix was fit by means of LISREL to a linear one-mediator model (b, c_1, c_2, and c_3 in Figure 1 were fixed to zero). The residual correlations are shown below the diagonal in Table 2. Note that the largest discrepancies in Table 2 are among variables Y_2, Y_3, and Y_4, which have nonlinearity (i.e., quadratic term, F^2, in Equation 1) in common. The residual correlation between X and Y_1 is also positive, since the best-fit single factor falls between F and F^2. This pattern of residuals is similar to that in Table 1.

A one-mediator model can be fit to the hypothetical data perfectly if the residuals for Y_2, Y_3, and Y_4 are allowed to be correlated. These correlations represent the shared nonlinearity of these variables. The model in Figure 1 thus fits the hypothetical data perfectly with b set to zero, by allowing correlations c_1, c_2, and c_3 to be nonzero (the values of c can be further constrained to satisfy Equation 10 of Birnbaum & Mellers, 1979).

This example illustrates that even when data are constructed from a single-mediator model, if some variables are nonlinearly related, deviations from the model can appear unless the model allows correlations among the residuals for nonlinear variables.

Table 2
Hypothetical Example for One-Mediator Nonlinear Model

	X	Y_1	Y_2	Y_3	Y_4
X		.69	.32	.39	.49
Y_1	.02		.32	.40	.51
Y_2	−.02	−.02		.26	.37
Y_3	−.03	−.02	.04		.40
Y_4	−.02	−.02	.06	.08	

Note. X = independent variable; Y_1 through Y_4 = dependent variables. Correlations are above diagonal; residuals from one-mediator linear model are below diagonal. Note similarity of residuals to those in Table 1.

Correlated Residual Model Fits Moreland and Zajonc Data

The model that fits the hypothetical data (Figure 2B) also achieves a good fit to the Moreland and Zajonc (1977) data (Figure 2A). It is a special case of a one-mediator model with nonzero correlations among the errors in the recognition variables. The correlations among the residuals (c_1, c_2, and c_3) may be given a response-bias, or "method," interpretation, since this model does not postulate any additional paths from stimulus frequency to any of the variables, besides the one via the recognition mediator (b is set to zero). The residual correlations from this one mediator model are quite small, the largest deviation being .04 for both experiments. The residual correlations between exposure frequency and liking are −.02 and .00 for Experiments 1 and 2, respectively.

Thus, the residual correlations from the linear one-mediator model may be attributed to shared nonlinearity of the recognition measures. This interpretation is consistent with the data shown in Figure 2A, with the pattern of residuals in Table 1 (in which the largest deviations involve recognition accuracy), and with the fact that the one-mediator model with correlated errors provides a good fit to the correlations. In sum, the one-mediator model remains a viable interpretation of the Moreland and Zajonc (1977) data if it is allowed that the recognition measures are nonlinearly related to the other variables.

Two-Mediator Model Not Required

The two-mediator model favored by Moreland and Zajonc (1979, Figure 1) yields the theoretical correlation matrix shown in the lower triangle of Table 3. The model is equivalent to Figure 1 of the present article with $c_1 = c_2 = c_3$ set to zero. Table 3 shows that if $b = 0$, each correlation can be represented as the product of correlations with the mediating variable, subjective recognition. However, with $b > 0$, the correlations between Y_1 (liking) and the others increase, especially the correlation between X and Y_1.

The hypothetical correlations generated from a two-mediator model in the upper portion of Table 3 show that in principle, it is possible to distinguish the two-mediator model from the one-mediator model. Note that the

Table 3
Theoretical Values for Two-Mediator Model and Hypothetical Example

	X	Y_1	Y_2	Y_3	Y_4
X		.75	.40	.40	.40
Y_1	$a_1a_2 + b$		.60	.60	.60
Y_2	a_1a_3	$a_2a_3 + ba_1a_3$		.64	.64
Y_3	a_1a_4	$a_2a_4 + ba_1a_4$	a_3a_4		.64
Y_4	a_1a_5	$a_2a_5 + ba_1a_5$	a_3a_5	a_4a_5	

Note. X = independent variable; Y_1 through Y_4 = dependent variables. Theoretical values are below diagonal. Hypothetical values above diagonal are based on $a_1 = a_2 = .5$, $a_3 = a_4 = a_5 = .8$, and $b = .5$.

hypothetical correlations of frequency, liking, and familiarity violate Equation 10 of Birnbaum and Mellers (1979), since $.75/.40 = 1.88$, which exceeds the limit set by $1/.60 = 1.67$.[1]

Table 4 shows parameter estimates and an index of fit for the various models under consideration, applied to data for Experiment 2 of Moreland and Zajonc (1977). To obtain the predicted correlation between two variables, multiply the coefficients along each path and sum these products over all distinct paths connecting the two variables in Figure 1. For example, for the one-mediator model, the predicted correlation between stimulus exposure and rated affect is a_1a_2, or .61. For the two-mediator model, the predicted value would be $a_1a_2 + b$, or .66.

The two-mediator model shown in Figure 1 of Moreland and Zajonc (1979) is equivalent to the model in Figure 1, with $c_1 = c_2 = c_3 = 0$. Because the models are mathematically identical, the index of fit in Table 4 ("χ^2") is the same as reported by Moreland and Zajonc (1979).[2] The largest residual for the two-mediator model for Experiment 2 is .13, between recognition confidence and recognition accuracy, a slight improvement over the corresponding value of .18 for the one-mediator model.[3]

The one-mediator model with correlated errors provides a better fit to the data than the two-mediator model, although it does not postulate an additional path from exposure to liking. The largest residual for this model is only .04 for both experiments. The value of χ^2 is less than one sixth as large as that for the two-mediator model. In addition, permitting b to be nonzero does not improve the fit, once correlations are allowed among the errors in the recognition measures (see last column of Table 4).

In sum, the analyses provide no compelling reason to reject the null hypothesis that b in Figure 1 is zero. Therefore, the data do not demonstrate the existence of another path from stimulus exposure to liking apart from

[1] The numerical example in Table 3 also illustrates that the two-mediator model predicts a larger correlation between X and Y_1 than would be predicted from the one-mediator model. According to the one-mediator model

$$\hat{\rho}_{XY_1} = \frac{(a_1a_3)(a_2a_3)(a_4a_5)}{(a_3a_4)(a_3a_5)} = \frac{\rho_{XY_2}\rho_{Y_1Y_2}\rho_{Y_3Y_4}}{\rho_{Y_2Y_3}\rho_{Y_2Y_4}}, \quad (2)$$

which reduces to a_1a_2. In contrast, the two-mediator theory with $b > 0$ predicts that the observed correlation should exceed the value of $\hat{\rho}_{XY_1}$ from Equation 2. For the values used in the hypothetical example of Table 3, Equation 2 (the one-mediator model) yields $\hat{\rho}_{XY_1} = (.40)(.60)(.64)/(.64)(.64) = .375$, which is only half as large as the table (two-mediator model) value of $\rho_{XY_1} = .75$. When Equation 2 is applied to the correlations of Moreland and Zajonc (1977), the values of $\hat{\rho}_{XY_1}$ are .48 and .81 for Experiments 1 and 2. The obtained values, which by the foregoing should have been *larger* than these values of $\hat{\rho}_{XY_1}$ according to the two-mediator theory, were only .42 and .66.

[2] The model comparisons presented by Moreland and Zajonc (1979) are based on chi-square values that may have been inflated by the assumption that by partialing out the main effect of subjects, the sample of 40 subjects produced 400 independent observations. However, repeated observations from the same subjects should not be treated as if they were independent. Since the computed chi-square is directly proportional to the assumed number of independent observations in each correlation, the "χ^2" values reported should not be used for statistical inferences. The "χ^2" values reported here are calculated using the same value (400) for the sample size, only to provide an index that can be compared with the accompanying article.

[3] Moreland and Zajonc (1979) fixed the coefficient of familiarity in both of their analyses even though it was actually estimated from their data (see their Footnote 2). As a consequence of this procedure the correct *df* for both models are 1 less than they report.

Table 4
Estimates of Parameters for Model Comparisons

Variable	Model			
	One mediator	Two mediator	One mediator correlated errors	Two mediator correlated errors
a_1	.82	.69	.86	.86
a_2	.74	.26	.77	.72
a_3	.74	.83	.68	.68
a_4	.42	.44	.37	.38
a_5	.57	.66	.45	.45
b	(0)	.48	(0)	.04
c_1	(0)	(0)	.04	.03
c_2	(0)	(0)	.25	.25
c_3	(0)	(0)	.25	.24
df	5	4	2	1
"χ^2"	83.58	38.99	6.22	6.22

Note. Based on data of Experiment 2 of Moreland and Zajonc (1977). Each entry represents estimated parameter as described in Figure 1, with restrictions imposed by the models. Values shown in parentheses are fixed. Degrees of freedom (df) are 10 minus the number of estimated parameters. The values of e_i are redundant; for example for the one-mediator model, e_i can be computed from $1 - a_i^2$. The "χ^2" is inflated and should not be used for statistical tests, but represents an index of fit that can be compared with values reported in the accompanying article.

an effect that could be mediated by stimulus recognition.[4]

It is always preferable to choose among theories on the basis of qualitative differences in predictions for a variety of experimental manipulations rather than on the basis of small differences in an index of fit. Perhaps evidence for a second mediator would occur if a new variable could be found that could potentially reverse the exposure effect, so that repeated exposure could either increase or decrease liking (while increasing recognition), depending on the value of the new variable. A future study may provide sound evidence that stimulus recognition does not mediate the exposure effect. Until such evidence is presented, however, it is premature to assert that there are two independent effects of stimulus exposure on liking.

Conclusions

These analyses do not disprove the possible existence of unconscious affect, learning without awareness, or subception. They do not disprove the favored interpretation of Moreland and Zajonc (1979), though the one-mediator model with correlated errors fits better than the two-mediator model without correlated errors (Table 4). However, the analyses do show that the null hypothesis of one mediator remains a viable description of the data of Moreland and Zajonc (1977), who argued that there are two independent effects. Perhaps the null hypothesis should be favored by skeptics and the burden of proof be laid upon those who would refute it.

[4] Moreland and Zajonc (1979) argued that if a single mediator explains their (1977) data, the mediator may be named "affect" rather than "recognition." The name of a mediator is a matter of definition that cannot be refuted by experiment. However, any discussion of the proper label for a single mediator is tangential to the original argument of Moreland and Zajonc (1977, p. 193). In that article they stated that evidence of two independent effects of exposure on liking was required to demonstrate that stimulus recognition is not necessary to the exposure effect.

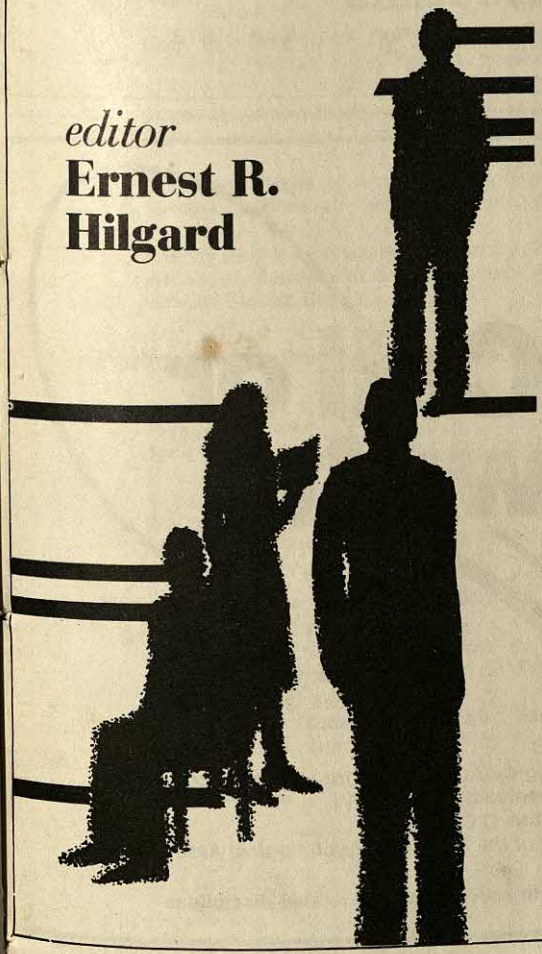
American Psychology in Historical Perspective

1892-1977

editor
Ernest R. Hilgard



Now available in one book — 21 APA presidential addresses in their entirety from some of the most important names in American psychology. Included are classic pieces from James, Cattell, Dewey, Thorndike, Woodworth, and Watson. You'll also find Harlow's "The Nature of Love" and Miller's "Analytical Studies of Drive and Reward."

This book is truly a milestone for historical psychology. It provides both a fascinating chronology of the presidents of the American Psychological Association from 1892 to 1977 and a valuable collection of significant essays.

This new APA publication traces the development of American psychology over four broad periods in psychology's history: the first 25 years (1892-1916), the years of the two world wars (1917-1945), the 20 years after World War II (1946-1967), and the recent past (1968-1977).

For each of these periods, the editor, Ernest R. Hilgard, provides a brief summary of the thinking in psychology at the time, biographies of all the APA presidents with abstracts of their presidential addresses, and the selected presidential addresses in full.

Sensitivity to Nonverbal Communication

The PONS Test

Robert Rosenthal, Judith A. Hall, M. Robin Di Matteo, Peter L. Rogers, and Dane Archer

The Profile of Nonverbal Sensitivity (PONS) is the first scientifically validated test for assessing the ability to decode nonverbal cues in various channels of communication. This book describes the PONS test and reports on the results of its widespread use. It has been administered to groups of children, teenagers, married couples, therapists, physicians, actors, mental patients, and others—a total of more than 7,000 people in a dozen different countries.

Based on their research with the PONS test, the test developers answer some new and some classic questions, including: Are women more accurate decoders than men? Are members of certain professions (e.g., actors, psychologists) exceptionally good at decoding emotions? Is nonverbal decoding correlated with general intelligence or cognitive skills? Are people accurate judges of their own nonverbal sensitivity? Does sensitivity predict success—for instance, are better decoders more popular or more effective in their work? $20.00

Resources in Environment and Behavior

NEW FROM APA IN 1979

An invaluable sourcebook for students, instructors, and researchers in the new field of environment and behavior. This solid reference includes:

- Overview and history of this emerging field
- Graduate programs—both formal and informal
- Teaching innovations introduced in the United States, Canada, and Great Britain
- Funding sources
- Career opportunities
- Directory of key individuals currently working in the field
- Annotated bibliography
- Listing of relevant journals

Resources in Environment and Behavior is available from the American Psychological Association for $10 (soft cover only). To order, make your check payable to APA.

American Psychological Association
Order Department

The Journal of Personality and Social Psychology publishes original reports of research, methodology, theory, criticism, and literature review in the fields of personality and social psychology of normal processes and populations. Submitted manuscripts should delineate an important question and provide a clear answer to it. In the case of research reports, this will often require demonstration that the reported results are generalizable beyond a single research setting. Consult the editorial in the January 1976 issue (Vol. 33, pp. 1–7) for a detailed statement of policies and instructions to authors.

Manuscripts: Submit manuscripts in quadruplicate, prepared according to the *Publication Manual of the American Psychological Association* (2nd ed.). Copies should be highly legible and will not be returned to authors unless they are original typewritten copies. Mail manuscripts according to instructions on p. 1249.

Required supplementary information: Manuscripts cannot be reviewed for publication unless the author provides supplementary information in the following categories: (a) a cover letter that indicates the relation (or the lack of relation) of the submitted manuscript to other papers by the same author(s) that are currently submitted, in press, or recently published; (b) one copy of each such related paper; (c) one copy of a statement of the procedures of the research reported in the submitted manuscript in sufficient detail to serve as a guide for conduct of an exact replication; and (d) one copy of the summary tables (e.g., correlation tables, analysis of variance summaries) for the *major* analyses reported. If it appears that the supplementary materials in categories (c) or (d) might be bulky, the author should exercise judgment and restraint in selecting what to send. It is not necessary to send supplementary material that repeats verbatim manuscript content.

After a manuscript is accepted, authors will be expected to provide assurance that their data are available in unanalyzed form for reanalyses by other investigators and that their research procedures were consistent with the American Psychological Association's published principles of research ethics, except insofar as may be detailed otherwise in the manuscript.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permission is normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of $10 per page, table, or figure. Abstracting is permitted with credit to the source. Permissions and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Permission and fees are waived for the photocopying of isolated articles for nonprofit classroom or library reserve use by instructors and educational institutions. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles with a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301. Address requests for reprint permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $60 domestic, $64 foreign, $6 single issue. APA member rate: $20. Write to Subscription Section, APA.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Published monthly in one volume per year by the American Psychological Association, Inc., 1400 North Uhle Street, Arlington, Va. 22201. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

The Stability of Behavior: I. On Predicting Most of the People Much of the Time

Seymour Epstein
University of Massachusetts—Amherst

One of the classic debates in psychology concerns the stability of personality. With rare exception, studies that have correlated objective behavior on two occasions have obtained coefficients below .30. Not only has the direct measurement of objective behavior failed to provide evidence of stability, but self-report scales in attitude and personality inventories, as well as ratings of behavioral samples by judges (although themselves stable), have produced low correlations with objective behavior. Does this indicate, as some have suggested, that stability of behavior lies primarily in the eye of the beholder? The issue can be resolved by recognizing that most single items of behavior have a high component of error of measurement and a narrow range of generality. In four separate studies it was demonstrated that when measures of behavior are averaged over an increasing number of events, stability coefficients increase to high levels for all kinds of data, including objective behavior, self-ratings, and ratings by others, and that objective behavior can then be reliably related to self-report measures, including standard personality inventories. The observation that it is normally not possible to predict single instances of behavior, but that it is possible to predict behavior averaged over a sample of situations and/or occasions, has important implications not only for the study of personality but for psychological research in general.

A critical issue in personality theory is whether stable behavioral dispositions, or traits, exist. On the basis of everyday observation, it seems evident to most people that they do. Yet the vast bulk of psychological research fails to provide confirmatory evidence. It must be concluded that either the lay view is right and our typical methods of research are lacking, or the research findings are correct and the lay view itself is a phenomenon worthy of study. Not surprisingly, psychologists of both persuasions can be found. The debate on the stability of personality, which is one of the classic debates in psychology, has recently been given new impetus by findings from statistical procedures that have suggested a resolution in the form of what has been called "modern interactionism." It will be demonstrated in this article that modern interactionism does not resolve the issue of stability of personality, no matter what other virtues it may have. A solution proposed in this article lies in an entirely different direction, one that is so obvious that, once pointed out, it reminds one of the fairy tale of *The Emperor's New Clothing*.

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3707-1097$00.75

Like the fairy tale, the implications of the solution go far beyond the immediate issue at hand.

This is not the place for a lengthy review of the debate. Excellent reviews and discussions are available in papers by Bowers (1973), Ekehammer (1974), Endler and Magnusson (1976), and Magnusson and Endler (1977). Allport (1937, 1961, 1966) can be referred to for a staunch theoretical defense of the trait position and Cattell (1965) and Eysenck (1969, 1970) for sophisticated, empirically based trait theories. The flavor of the attacks on the trait position can be represented by the following quotations spanning the period of the debate.

> Training the mind means the development of thousands of particular, independent capacities, the formation of countless particular habits, for the working of any mental capacity depends upon the concrete data with which it works. Improvement in any one mental function or activity will improve others only in so far as they possess elements common to it also. The amount of identical elements in different mental functions and the amount of general influence from special training are much less than common opinion supposes. (Thorndike, 1906, p. 248)

> Over and over, a battery of tests designed to measure traits such as persistence, or aggressiveness, or honesty yields results so unreliable and undependable (when compared with other criteria) that one is led to question the actual existence of the general trait. In numerous instances the instruments are very loosely constructed and are clearly equivocal. A survey of . . . a wide variety of frequently used tests suggests that there is a fundamental limitation common to most of them. Trait testers appear to assume that whatever they name has objective reality; many need not so much to improve their measures but to improve or change their thought regarding traits. (Lehman & Witty, 1934, p. 49)

> The generality of these (personality) measures over method and situation was still not high enough to justify perpetuating the traditional concepts of personality. The findings required abandonment of a line of research to which I had devoted ten years of my life as a psychologist. The results also required a change in beliefs about the nature of personality. This research, per se, did not say which way the conceptual shift should go, but it suggested very strongly that traditional conceptions of personality as internal behavior dispositions were inadequate and insufficient. (Peterson, 1968, p. 23)

> With the possible exception of intelligence, highly generalized behavioral consistencies have not been demonstrated, and the concept of personality traits as broad predispositions is thus untenable. (Mischel, 1968, p. 146)

> As noted earlier, there was nothing silly about the initial assumption of personologists that everything was glued together until proved otherwise. But since it has now proved otherwise, it seems only fair to give a sporting chance to the counter-assumption that nothing is glued together until proved otherwise. Instead of assuming cross-situation correlations to be +1.00, let us begin by supposing them to be 0.00 until we can explicitly construct them to be otherwise. (Bem, 1972, p. 25)

The charge that personality traits do not exist clearly strikes at the very heart of personality theory. One could well argue that if individuals do not have relatively stable behavioral dispositions that differentiate them from other individuals, then the concept of personality itself can be dispensed with. Shweder (1975), in fact, comes close to arguing just that.

> The degree of relevance of the concept "personality" constructed in this "individual difference" sense is questioned. Some of the most ubiquitous personality assessment procedures, specifically interpersonal checklists, personality inventories, and questionnaire interviews are shown to be subject to a form of systematic bias which creates the "illusion" that the diversity of individual behavioral differences can be reduced to a limited set of person-distinguishing underlying forces (traits, dispositions, scales, factors or dimensions). (p. 455)

As will be seen shortly, the claim of such bias is one of the main arguments raised against the trait position, as it can explain

---

This article and three of the studies reported in it were supported by National Institute of Mental Health Research Grant MH-01293. It was distributed in mimeographed form in May 1977.

I would like to acknowledge my indebtedness to Edward O'Brien for several of the historical quotations included in this acticle, for drawing my attention to findings in the Hartshorne and May studies that provide evidence for stability in personality, and for the quotation to that effect. The information was contained in a paper by O'Brien on stability in personality that he wrote as part of his comprehensive examination for his PhD degree at the University of Massachusetts.

I also wish to express my appreciation to James Averill, Icek Ajzen, Seymour Berger, Ronnie Janoff Bulman, Alice Eagly, Howard Leventhal, and Ervin Staub, for their helpful comments on an earlier draft of this article.

Requests for reprints should be sent to Seymour Epstein, Department of Psychology, University of Massachusetts, Amherst, Massachusetts 01003.

why there are data from self-report inventories and ratings by others in support of stability in personality but not such data from the direct, objective measurement of behavior.

Arguments For and Against the Existence of Traits

Not surprisingly, given attacks on the very foundation of personality theory such as those cited above, some lively debate has ensued. Others who have joined the fray include Alker (1972), Argyle and Little (1972), Averill (1973), Campus (1974), Cronbach (1957, 1975), Endler and Hunt (1968, 1969), Epstein (1977), Fiske (1961), Moos (1969, 1970), Olweus (1977a), Pervin (1968), Raush (1965), Sarason (1977), Schalling (1977), Vale and Vale (1969), Vernon (1964), Wachtel (1973), and Zuckerman (1977). It is not our intention to review the position of each here. For present purposes, it will suffice to list the arguments and the kind of evidence cited for and against traits.

Situationist Position

According to the situationist position, there is little stability in personality, as behavior is determined almost exclusively by situational variables. The belief that there is little stability in personality rests on three major sources of evidence. The most important is that when behavior in one situation is correlated with behavior in another situation, the correlations are so low—usually less than .30—that they have been disparagingly referred to by Mischel (1968) as "personality coefficients." Mischel (1969) further notes, "A correlation of .30 leaves us understanding less than 10% of the relevant variance. And even correlations of that magnitude are not very common and have come to be considered good in research on the consistency of any noncognitive dimension of personality" (p. 1012). At the same time there is no dearth of evidence that behavior varies markedly as a function of stimulus or situational variables.

A second source of evidence consists of findings from the apportionment of variances in analysis of variance designs. This procedure was independently introduced into the assessment of stability in personality by Raush and his colleagues (Raush, 1965; Raush, Dittman, & Taylor, 1959; Raush, Farbman, & Llewelynn, 1960) and by Endler, Hunt, and their colleagues (Endler, 1966; Endler & Hunt, 1968, 1969; Endler, Hunt, & Rosenstein, 1962). They and others since (e.g., Argyle & Little, 1972; Ekehammar & Magnusson, 1973; Magnusson, 1971; Moos, 1968, 1969, 1970; Magnusson, Note 1) have demonstrated that the variance attributable to individual differences is usually much smaller than the variance attributable to situations and to the interaction of individuals and situations.

A third source of evidence cited by situationists is that when people rate others, they tend to attribute more stability to individuals across situations than is objectively warranted (e.g., Bem & Allen, 1974; Jones & Nisbett, 1971; Mischel, 1968; Shweder, 1975). This, of course, can explain how there can be a widespread belief in the stability of personality when, in fact, there is little stability. The study of such bias in person perception has itself become a significant area of research, and has produced a quantity of explanations as to why the phenomenon of falsely perceiving stability in personality occurs. For example, it has been suggested that (a) it is emotionally satisfying to believe that behavior is predictable, particularly when it is someone else's; (b) it is simpler to classify behavior by people than by situations; (c) people have implicit personality theories that assume stability in personality, and their theories bias their perceptions; (d) a primacy effect operates to make new impressions conform to old ones; (e) the observer is always present in the situations that he or she observes in real life, thereby presenting the observer with a biased sample; (f) there is a tendency for observers to equate behavior that elicits the same emotional reactions in them; (g) there is a tendency for judges to generalize from a few attributes that are stable, such as intelligence, to others that are not; and (h) there are more terms for classifying people than for classifying situations, which leads to a bias toward attributing

behavior more often to characteristics of people than to characteristics of situations.

Trait Position

The arguments that have been advanced in favor of traits amount primarily to conjectures that if different procedures had been followed in the investigations of stability in personality, higher stability coefficients would have been found. There are also a few studies that can be cited that obtained respectable stability coefficients.

The arguments can be summarized as follows: (a) Many of the studies undertaken to assess stability in personality have been experimental studies, which are better suited to demonstrate change than stability in personality (Bowers, 1973). (b) The unit of analysis is a critical factor that has not been adequately taken into account. What appears to be instability at a phenotypic level of analysis may be stability at a genotypic level (Alker, 1972; Bowers, 1973). To use one of Bowers' examples, a woman who is continuously changing her wardrobe may be consistently fashionable. (c) The use of moderator variables would considerably increase reliability coefficients (Alker, 1972). (d) A failure to recognize that some people are more variable than others results in reporting generally low stability coefficients, rather than in noting that at least some individuals are highly stable (Alker, 1972; Bem & Allen, 1974). There is at least one study (Bem & Allen, 1974) that has demonstrated this effect. (e) In everyday life, people determine their own environment, which, in turn, helps maintain the stability of their personality. The operation of this effect is not possible in laboratory studies in which individuals are arbitrarily assigned to conditions (Bowers, 1973; Wachtel, 1973). (f) Stability in personality is mediated by an individual's cognitions and, accordingly, will only be found when ideographic procedures are used that take into account the subjective nature of perception (Alker, 1972; Bem & Allen, 1974; Bowers, 1973; Mischel, 1973). (g) Stability may be demonstrable to a greater extent in within-subject relationships than in between-subjects relationships (Alker, 1972). Carlson (1971) makes a related point in noting that although the concept of personality implies an organization of variables within an individual, among a large number of studies she reviewed, "*not a single published study attempted even minimal inquiry into the organization of personality variables within the individual*" (p. 209).

As to studies that have reported evidence for stability in personality, we will not consider investigations relying on self-report inventories, as such studies can simply demonstrate that people's beliefs about their behavior are consistent, which is a far cry from demonstrating that the behavior itself is consistent. Nor will an attempt be made to review all behavioral studies that have reported positive findings. Our purpose will be served adequately by a review of three series of carefully conducted studies. On the basis of the findings in these studies, it is possible to formulate an integrative hypothesis that can account for all the known results to date. This will be followed by a presentation of four studies that were explicitly undertaken to test the hypothesis.

Block (1971, 1977) conducted a series of studies in which the stability of a variety of personality variables was examined during different periods between childhood and adulthood. In one set of studies, records were obtained from the archives of the well-known longitudinal studies at Berkeley of the behavior of students when they were in junior and senior high school. The subjects were then intensively interviewed when they were in their mid-thirties. Judges rated each subject for the different periods on the items in the California *Q* Set (Block, 1971). To ensure that stability coefficients would not be artificially inflated by response sets, memory, or other sources of rater bias, different judges rated the subjects at the different time periods. For the period from junior to senior high school, 58% of 114 personality variables produced stability coefficients that were at least as high as .35, which is significant at the .001 level. Some of the correlations were as high as .70. For the period from senior high school to age 30 and above, 29% of 114 personality variables yielded stability coeffi-

cient of .35 or greater, with some as high as .61.

In a study of younger children by Block and Block (Block, 1977), observations were made during the children's 4th, 6th, and 8th years of life. Two or three judges, who were the children's nursery school teachers, observed the children for 3 hours a day over a period of 5–9 months and then rated each child on a modification of the California *Q* Set. Rater bias was controlled by having different teachers rate the children at different periods. The average stability coefficient for 100 *Q* items was .48, with several over .60, and a few as high as .70. When the *Q* items were grouped into broader scales by factor analysis, the mean stability coefficients rose to .56.

In a series of studies on aggression in young boys, Olweus (1973, 1974, 1977a, 1977b) had classmates rate 201 boys in the 6th grade, and again 3 years later, on a number of variables pertaining to aggression, such as tendency to start fights with peers. Ratings for each boy were averaged over 3–10 raters. Memory effects and response bias were evaluated and controlled by statistical procedures and by examining subgroups in which there was no overlap in raters. The mean stability coefficient for the 3-year period was .66. When correlations were corrected for attenuation due to rater unreliability, the stability coefficients rose to about .80. In a second similar study in which 85 13-year-old boys were the subjects, even higher stability coefficients were obtained. In other studies in the series, it was observed that peer ratings, teacher ratings, and self-ratings on a specially designed aggression inventory were all highly intercorrelated, suggesting the existence of a broad dispositional trait of aggression.

The classic series of studies by Hartshorne and May (1928, 1929) and Hartshorne, May, and Shuttleworth (1930) on honesty, often cited as evidence against the existence of stability in personality, was an enormous project that spanned half a dozen years, employed a large team of researchers, and tested a national sample of over 8,000 children. Among the behavioral items that were assessed were cheating in a classroom, cheating on a take-home examination, cheating during a game, stealing money, lying, and falsifying records of athletic performance. The average intercorrelation of 23 subtests used as part of a total character score was found to be .23, which led Hartshorne and May to conclude that honesty in any single situation has low predictive value for honesty in any other single situation. This conclusion is invariably cited as evidence against the existence of stability in personality. What is generally not known is that when Hartshorne and May combined several tests of honesty into a single score, the reliability coefficient increased to .73, and they concluded,

> Just as one test is an insufficient and unreliable measure in the case of intelligence, so one test of deception is quite incapable of measuring a subject's tendency to deceive. That is, we cannot predict from what a pupil does on one test what he will do on another. If we use ten tests of classroom deception, however, we can safely predict what a subject will do on the average whenever ten similar situations are presented. (Hartshorne & May, 1928, p. 135)

Further support for the existence of a broad trait of honesty in the Hartshorne and May data is provided by a factor analysis by Burton (1963), who observed that a general factor of honesty accounted for nearly 50% of the total variance.

Interactionist Position

According to the interactionist position, the question of which is more important, the situation or the person, is a meaningless one, as behavior is always a joint function of the person and the situation. In its applicability to the issue of stable individual differences, the interaction position can be viewed as a compromise between the trait position and the situationist position, for it acknowledges the existence of behavioral stability, but only within situational constraints.

The so-called modern interactionist position was derived from findings on apportioning variances in an analysis of variance design. As already noted, it was observed by a number of psychologists that the interaction of individuals and situations accounted for more variance than either source of variance by itself. It was consequently argued that an interactionist position should supplant both the trait and the situationist position (Bowers,

1973; Ekehammer, 1974; Endler, 1966; Endler & Hunt, 1968; Magnusson, Note 1).

As for a more general interactionist viewpoint that goes beyond statistical interaction (see Magnusson & Endler, 1977, for a thorough review of this position), it is assumed that individuals and situations are interdependent. That is, the individual's cognitions and perceptual processes, as much as the objective characteristics of the stimulus, determine the meaning of the stimulus. From this viewpoint, behavior can best be viewed as a transaction between the individual and the stimulus, each influencing the other. Since behavior never takes place in a vacuum but always occurs in a situational context, it is meaningless to talk about characteristics of an individual's behavior without specifying the situation in which the behavior occurs. To understand and predict behavior, it is, accordingly, just as necessary to have a classification system for situations as for individuals and, most important, to know how individuals interpret different kinds of situations.

Evaluation of the Arguments For and Against the Existence of Traits

Evaluation of the Situationist Position

The case of the situationists against traits rests mainly on empirical grounds. They note that the concept of traits is not unreasonable but add that it is also not supported by the facts. The strongest evidence they cite against traits consists of the low stability coefficients obtained when data are derived from direct behavioral measurement. However, it is important to recognize that in almost all cases the correlations were based on single items of behavior. Such correlations actually have little relevance for the existence of traits, as no trait theorist believes that a trait can be inferred from a single instance of behavior. A trait is a generalized tendency for a person to behave in a certain manner over a sufficient sample of events and does not imply that he or she will exhibit trait-relevant behavior in all situations or even on all occasions in the same situation. From another standpoint, single items of behavior have a high component of error of measurement, thereby limiting the possibility of replication, and a high component of situational uniqueness, thereby limiting the possibility of generalization. It is no more reasonable to assess the stability of nonintellective behavior by correlating single observations than it is to assess the stability of intellective behavior by correlating single items in an intelligence test. Thus, for statistical reasons alone, the low correlations cited as evidence against the existence of stable response dispositions can be discounted.

The view that there are traits consisting of relatively broad, stable, behavioral dispositions does not require the assumption that situations do not affect behavior. Behavior can vary significantly with situations, and there can still be an underlying consistent thread in behavior averaged over situations. Thus, demonstrations that behavior varies with situations or even that it varies more with situations than with individuals cannot be taken as evidence against the existence of traits.

Let us now consider the procedure of apportioning variances in an analysis of variance design, on the basis of which it has been claimed that there is little stability in personality. It has been falsely argued that if there were stability in personality, individual differences would necessarily account for a relatively large proportion of total variance. This argument is fallacious for two reasons. First, the proportion of variance attributable to any one factor, such as individuals, is always influenced by the range of variability represented by the other factors. Thus, if situations are selected over a wide range of variability and individuals over a narrow range, the proportion of variance for individuals will be smaller than that for situations. It is evident that depending on how one selects individuals and situations, and how the two are selected in relationship to each other, individuals, situations, or their interaction can be made relatively large or small. Second, the analysis of variance has been misused in obtaining estimates of stability, for instead of using the appropriate error term for obtaining estimates of stability coefficients, the variance for individual differences has been compared to total variance

(see Epstein, 1977; Golding, 1975; Olweus, 1977; Magnusson, Note 1, for a further development of this point on the misuse of analysis of variance). It is possible with such a procedure for individuals to be perfectly reliable over time, as indicated by a reliability coefficient of +1.00, and yet have individual differences contribute a relatively small proportion of total variance. For example, consider a situation in which all individuals come out exactly the same in a 50-yard dash and in a 500-yard dash. As the mean difference between events will be many times greater than the differences among racers within events, it is evident that the variance due to individuals will be a small proportion of the variance due to situations, let alone of the total variance.

The argument that judges sometimes attribute stability to people that is not there describes an interesting phenomenon, but cannot establish that there is no stability in behavior apart from such bias. In fact, the assumption that under most circumstances there is stability in personality can account for a bias to assume there is stability even when there is not. Further, the same factors that contribute to the perception of stability in personality could also contribute to its actual stability. If it is assumed that there is a fundamental need for people to establish orderliness and predictability in the world of their experience and that they accomplish this through their cognitions, including their habits of perception (see Epstein, 1973, Note 2; Mischel, 1973), then the same cognitions and perceptions could contribute not only to people's ratings of stability but to the stability of their actual behavior as well.

Finally, it should be recognized that the null hypothesis cannot be proven by the failure of many studies to demonstrate stability in personality. The possibility remains that with new understanding and new approaches, the conditions for demonstrating stability in objectively measured behavior will be established.

Evaluation of the Trait Position

The arguments in defense of traits are, for the most part, speculations that if things had been done differently, stability in personality might have been demonstrated. Although the proposals may be of interest in suggesting new directions for personality research, they do not constitute an adequate defense of the position that there is stability in personality. All these proposals can do is indicate that the issue should not be closed until they have been tried. Unfortunately, though some of these proposals have been tested, they have failed to fulfill their promise (Bem, 1972). In our own research, in which we compared mean within-subject correlations to between-subjects correlations for the same variables, we have generally found the former to yield smaller values.

Finally, one must agree with Bem (1972) that the issue of stability in personality cannot be resolved by disputation but only by data, "And if these separate indices permit Alker to predict behavior across situations better than +.30, Mischel will fold up his tent and steal away" (p. 18).

How is one to evaluate the findings in a few studies that have demonstrated stability in behavior in comparison to the vast number of studies that have obtained negative findings? One possibility is that when enough studies are done, a few are bound to produce significant results by chance alone. An alternative is that the few studies that produced positive findings were better conceived and conducted than the many that failed (see Block, 1977). A careful analysis of the studies that succeeded could uncover the critical conditions for demonstrating stability in behavior. It is noteworthy, in this respect, that all three series of studies that succeeded examined relatively extensive samples of behavior. In the series of studies reported by Block (1971, 1977) and by Olweus (1973, 1974, 1977a, 1977b), judges rated behavior over a relatively long period. In the Hartshorne and May studies (1928, 1929), reliability was found only when a sufficient number of behavioral items was combined into a single index. As previously noted, single items of behavior, like single items in a test, tend to have a high component of error of measurement. Thus, it may be that procedures for reducing error of measurement are critical for demonstrating stability in

personality. Further evidence in support of this conjecture is that in the studies by the Blocks and by Olweus, ratings from several judges were combined, which is one means of reducing error of measurement. In addition, the Blocks found that when they combined a number of single measures into a broader one, stability coefficients markedly increased, a finding also reported by Hartshorne and May. Thus, a possibility that must be considered is that the critical factor separating the studies that succeeded in establishing stability from those that failed to do so is the steps taken to reduce error of measurement by obtaining adequate samples of behavior in the former studies.

Evaluation of the Interactionist Position

As already noted, there have been problems with the statistical and methodological procedures employed by the interactionists. Moreover, the claim that the interaction of individuals and situations accounts for more variance than either individuals or situations alone has not been uniformly upheld (see Sarason, Smith, & Diener, 1975). In a review of a large number of studies, Sarason and his colleagues found that individuals, situations, and their interaction did not account for very much of the total variance. Rather, the predominant source of variance was error variance. Thus, which of the first three sources of variance is most important is a moot point, as often none accounts for a satisfactory amount of variance.

The more general interactionist position does not involve so much a new position as a rewakening of interest in an old position (see Ekehammer, 1974). Murray (1938), in his classic studies of personality, not only endorsed an interactionist view at a theoretical level, but developed a classification system for response tendencies and for subjectively and objectively defining stimulus situations. Even more to the point, his concept of thema identified a unit of interaction between a response disposition and a stimulus variable. There is little question but that behavior is a joint function of the person and the situation. However, this is irrelevant to the question of whether a reasonable degree of stability in individual behavior can be demonstrated when the behavior is averaged over a sufficient sample of situations. It is noteworthy, in this respect, that interactionists have been no more successful than others in breaking the .30 personality barrier. If they are to succeed in doing so, they will have to obtain a sufficient sample of people in particular situations. That is, interactionism does not replace the need to reduce error of measurement by sampling, but simply determines what it is that must be sampled, namely people with certain attributes in situations with certain attributes. It can be anticipated, of course, that to the extent to which situational as well as personality variables are taken into consideration, the amount of averaging over occasions that is required for a fixed level of temporal reliability will be reduced.

Resolution of the Three Positions and the Proposal of an Integrative Hypothesis

The trait position, the situationist position, and the interactionist position are often presented as three different approaches to the issue of stability in behavior, with the implication that only one of them can be right. Actually, all of them can be right, because they identify not three different solutions to the same problem but three different problems. The interactionist wishes to study the behavior of people with certain attributes in situations with certain attributes. The trait theorist wishes to study consistent behavioral tendencies in individuals over a sample of situations. The situationist is concerned with the general effects of situations over a sample of individuals, for example, the educator who seeks to determine the most effective method for teaching most pupils to read and the architect who seeks to determine the design for a structure that will please the most people. In other words, for certain purposes it is important to predict behavior of people with certain attributes in situations with certain attributes; for other purposes it is important to predict a person's behavior over a sample of situations; and for yet other purposes it is important to predict the influence of a specific situation on a sample of

people. Underlying all approaches is the need to consider that error of measurement is apt to be high and temporal reliability, or replicability, low when findings are derived from single observations. This is so because of the contribution of unassessable factors of "situational uniqueness" that are apt to be present on any one occasion. (Situational uniqueness will be further discussed in the second article in this series; see Epstein, Note 2.) By averaging over situations and/or occasions, error of measurement can be reduced and temporal reliability increased. Without temporal reliability, meaningful generalization cannot be established, and this applies equally to the demonstration of stable effects for individual differences, for situations, and for their interaction.

The main focus of this article is the stability of individual differences. If our assumption about reducing error of measurement through averaging over observations is correct, it should be possible to routinely break the presumed .30 personality barrier by averaging behavior over a sufficient number of events. It should be noted that this was done implicitly in the studies by the Blocks and by Olweus, as when a judge makes a single rating after observing a child on many occasions, the single rating can be viewed as an intuitive averaging.

The above analysis of what is necessary to demonstrate stability in behavior, simple as it is, is different from previous explanations that have assumed that the crucial factor is the kind of data obtained. Thus, Block (1977) noted that there is impressive evidence for the stability of personality in ratings by judges of real-life behavior (R data) and in self-reports (S data) and that there exists impressive evidence for the coherence of the two forms of data. He further observed, however, that there is no evidence for stability in personality when the data consist of the direct measurement of objective behavior (T data) and that such data are, at best, tenuously related to the other two kinds of data. Block concluded, "It is now incumbent upon us to consider . . . what strategies are likely to extend the realm of coherence so as to include as well the domain of T-data" (p. 63). Mischel (Note 3) also expressed concern over the lack of relationship between objective data and data derived from ratings by others and from self-report. He stated,

> An important test, although surely not the only one—of the utility of constructs about personality dispositions remains their ability to predict the individual's behavior in specific situations. Unless R and S data predict T data appreciably, the links between trait impressions and specific behavior-in-situations remains tenuous. (p. 4)

If our reasoning is correct, the following hypothesis and corollary should define the conditions for routinely establishing stability in all kinds of data, including ratings by others, self-ratings, and objective behavior, and for relating ratings by others and self-ratings to objective behavior.

Hypothesis

Stability can be demonstrated over a wide range of variables so long as the behavior in question is averaged over a sufficient number of occurrences. This applies equally to data derived from the direct measurement of objective behavior, from self-reports, and from ratings by others.

Corollary

Reliable relationships can be demonstrated between ratings by others and self-ratings, including standard personality inventories on the one hand and objective behavior on the other, so long as the objective behavior is sampled over an appropriate level of generality and averaged over a sufficient number of occurrences.

Empirical Testing of the Hypothesis and Corollary

A series of studies has been completed that examined the temporal reliability and in some cases the validity of data derived from self-observation, observation by others, and the direct measurement of objective behavior. In all cases, a similar procedure was followed, that is, behavior was observed on several occasions, and single observations were treated like single items on a test. More specifically, stability coefficients were first determined for

a 1-day sample by correlating each subject's scores on Day 1 with each subject's scores on Day 2. Next, coefficients were determined for a 2-day sample by correlating the mean of a subject's scores on Days 1 and 3 with the mean of the subject's scores on Days 2 and 4, and so on, until the mean of a subject's scores on all odd days was correlated with the mean of the subject's scores on all even days. This made it possible to examine split-half stability coefficients for each variable as a function of the number of observations that were averaged. Such a procedure is analogous to that which compares the reliability coefficients of tests of different lengths.[1]

Study 1: Stability of Self-Recorded Data

Method

Study 1 used data available from a previous investigation of emotions in everyday life. The selection of variables in the study was influenced by a theory of the self-concept that assumes that a person's significant postulates about self and world can be inferred from events that elicit emotions (Epstein, 1973, 1976, in press). For 1 month 14 men and 14 women university students kept records, on specially devised forms, of their most pleasant and unpleasant experience each day. At the end of each week, they met with interviewers who answered their questions and checked for errors. The number of recording days completed by subjects varied from 24 to 34. The first page of each form consisted of a blank page for describing the incident in narrative form. This was followed by a 90-item adjective checklist for recording emotions and a 66-item checklist for recording response tendencies and for noting whether they had been carried out. Emotions and impulses were scored on a 4-point scale for intensity, with a blank signifying zero intensity. Behavior carried out was scored on a 2-point scale for carried out or not carried out. Items were collapsed into broader scales by a factor analysis of the data. These broader scales constituted the data that were analyzed in the present study. As an example of a scale of emotions, worthy included the following six adjectives: adequate, competent, appreciated, respected, pleased with self, and proud. As an example of a scale of response tendencies, stimulus seeking included the following three items: to try something new and adventurous; to take risks, to gamble, to seek stimulation; and to seek thrills and excitement. Scores were obtained by averaging the responses to the items in a scale.

As an afterthought, it was decided to score the narratives for the stimulus conditions, or situational factors, responsible for evoking the emotions. Despite successive modifications of Murray's (1938) system for scoring Thematic Apperception Test protocols and intensive training of judges, it was not possible to obtain satisfactory interscorer reliability coefficients, as information necessary to make decisions was often unavailable. Rather than drop the scoring of situational factors, it was decided to retain it, with the realization that whatever results were obtained on the stability of situational factors would underestimate the true stability but would nevertheless be of some interest in indicating a lower limit of such stability.

Results

Between-subjects reliability coefficients: The stability of individual differences. In Table 1, stability coefficients for pleasant experiences are presented for the mean of all odd days compared to the mean of all even days, for Day 1 compared to Day 2, and for the last day compared to the next-to-last day. Also included are the means and standard deviations for all variables for the data averaged over all days. Table 2 presents the same data for unpleasant experiences. It can be seen in both tables that for a 1-day sample, most reliability coefficients are below .30, and this is true for the last 2 days as well as for the first 2 days, indicating that a bias toward greater stability did not develop over the course of the study. On the other hand, when the mean of all odd days is correlated with the mean of all even days, most coefficients are above .70, and some are above .90. Emotions, which were the central focus of the study and on the basis of which events were selected by the subjects, had the highest stability coefficients, with a mean of .79 for unpleasant emotions and of .88 for pleasant

[1] A related procedure is reported by Patrick, Zuckerman, and Masterson (1974; also see Zuckerman, 1976). They administered an adjective checklist to a class on 13 occasions. They then examined the correlations of responses over an increasing number of days with the sum of the responses over all days. Not surprisingly, as the number of days increased so did the correlations with total days, until a perfect correlation was obtained when the data over all days were correlated with themselves. Of greater interest is the form of the curve, which was negatively accelerated. Correlations increased rapidly over the first 3 days, after which increments became relatively small. This indicates that for data such as those examined in the study, aggregating over three occasions can effectively predict the results for a much larger number of observations.

emotions. It is not evident why positive emotions should produce higher reliability coefficients than negative emotions, but this finding has held up in all further studies. Perhaps subjects are more confused about their negative than their positive feelings.

As expected, the lowest reliability coefficients were obtained for situations. Yet, even here, the mean correlation was well above the .30 barrier, more than half the correlations were significant at the .01 level, and several were above .70. The finding of stable

individual differences for situational variables is consonant with the view that an important source of stability in personality is that people create stable environments for themselves (Bowers, 1973; Wachtel, 1973).

Figure 1 presents mean stability coefficients averaged over all variables in a category as a function of the number of days in the sample. In all cases, correlations are relatively low for a 1-day sample, rise sharply as the number of days in the sample is increased, and then approach an asymptote. Figure 1 can be used to determine how many observations are necessary to obtain different levels of reliability. It can be seen, for example, that for unpleasant emotions, a 4-day sample is required for a mean stability coefficient of about .50 and a 10-day sample for a mean coefficient of about .75.

The most obvious explanation of the increase in reliability with averaging over increasing observations is that the averaging reduces error of measurement. This explanation can be tested by examining standard deviations as a function of the number of days averaged. In Figure 2 it can be seen that for all categories, there is an initial sharp decline in standard deviation as a function of increasing observations, followed by a gradual approach to an asymptote. The curves, to a large extent, are an upside-down reflection of the curves for the correlations in Figure 1. As the correlations get larger, the standard deviations get smaller. This indicates that the variance being eliminated is within-subject variance, which from the viewpoint of the present study (where concern is with establishing stable individual differences), can be regarded as error variance.

To what extent are the findings on stability coefficients limited because the data consist of self-report statements? Such a question misses the point, which is to demonstrate that in a condition where a high level of stability can be shown to exist by adequate sampling, it would not be found if only a single event had been observed. It follows that the vast majority of studies that have failed to find stability in personality when comparing behavior on single occasions used procedures incapable of demonstrating stability. In any event, other studies, reported later, indicate that the results are not limited to self-report data.

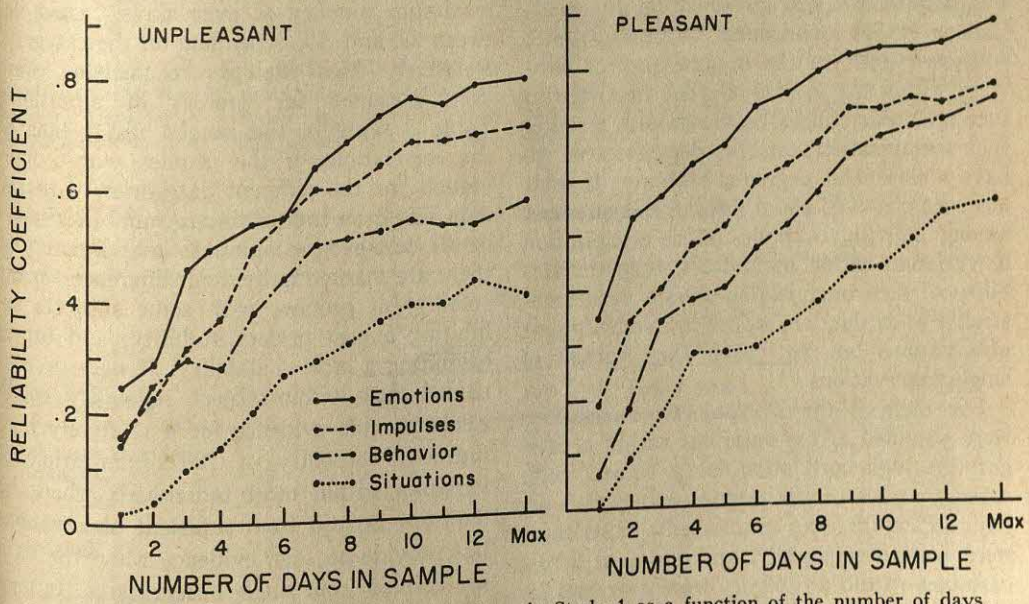

Figure 1. Between-subjects reliability coefficients in Study 1 as a function of the number of days in the odd–even samples. (Values plotted represent the mean of the correlations for the variables in a category. [From "Traits are Alive and Well" by S. Epstein. In D. Magnusson & N. S. Endler (Eds.), *Personality at the crossroads: Current issues in interactional psychology*. Copyright 1977 by Erlbaum, Hillsdale, N.J. Reprinted by permission.])

Within-subject reliability coefficients: The stability of the organization of variables within an individual. No matter what else personality is, it is widely recognized that it involves an organization of variables within an individual. Yet, despite universal agreement on this point, Carlson (1971) found not a single study that addressed itself to the organization of variables within the individual. The first step in such an inquiry might be to establish whether such organization can be demonstrated to have a reasonable degree of stability. If what has been observed about error of measurement among individuals applies to the organization of variables within individuals, then the stability of such organization should be demonstrable when data are averaged over sufficient observations but not when they consist of single observations.

For each of the 28 subjects, correlations were obtained across variables within a category. A high correlation for a subject indicated that his or her profile was stable over days. Pleasant and unpleasant experiences were treated separately, and the data across variables within a category were averaged for different numbers of days. It can be seen in Figure 3 that when profiles were derived from single observations, the average intrasubject stability coefficient was less than .25 over all categories. As the number of days from which individual profiles were derived was increased, the stability coefficients also increased. The average correlation for profiles based on the maximum number of odd days versus the maximum number of even days varied between .60 and .79, depending on the category. Relatively high stability coefficients were even obtained for profiles of situations. Table 3 presents the ranges and means of the correlations of the profiles within individuals for the different categories, with the data based on the maximum number of days in the odd–even samples. It is apparent that there are marked individual differences in the stability of profiles, with some subjects exhibiting almost perfect stability, and others exhibiting a lack of stability. It may be concluded that within-subject reliability coefficients provide evidence for a relatively high degree of stability of the organization of variables within most individuals when the data are derived from sufficient observations but provide no such evidence when the data are derived from single observations. It may further be concluded that there are marked individual differences in the degree to which individuals exhibit stability in their personality profiles.

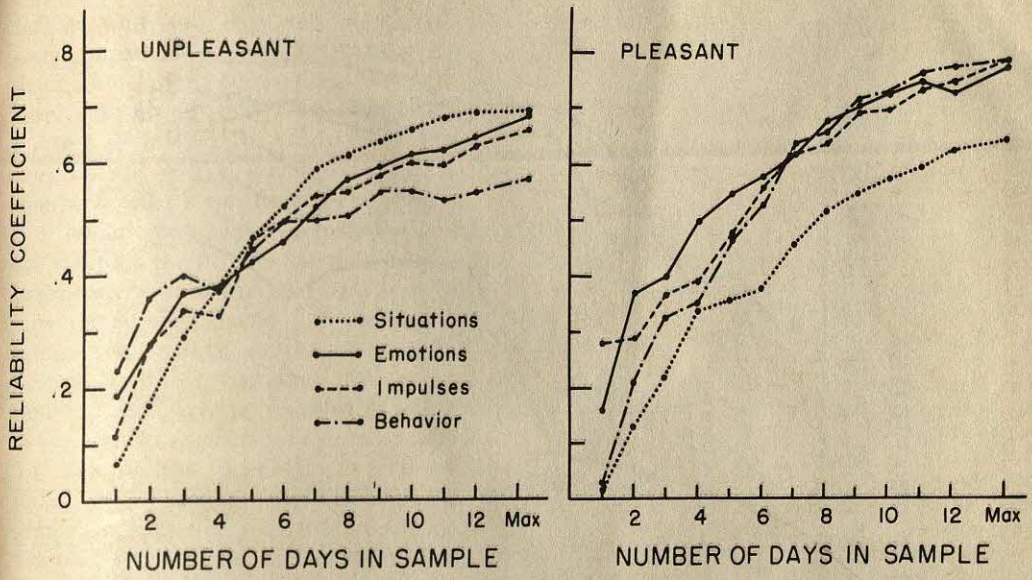

Figure 3. Within-subject reliability coefficients as a function of the number of days in the odd–even samples in Study 1. Study 2: Stability of Behavior Observed by Others

Method

The data for this study were obtained from an investigation by Barry Leon (Note 4) of social and impulsive behavior in everyday life. Thirty-two pairs of women students at Smith College served as subjects and observers in the study. For a couple to be selected, the observer had to have ample opportunity to observe the subject during and outside of class. The observer kept records of the subject's behavior on eight items related to impulsivity and sociability. Ratings were made on 3-point scales for frequency of occurrence. The following is an example of one of the items: "She actively sought out the company of others: (a) never, (b) once or twice, or (c) three or more times."

Table 3
Means and Ranges of Within-Subject Odd–Even Reliability Coefficients for Maximum Number of Days Sampled in Study 1

Category	*n*	Least reliable subject within category: Subject no.	Least reliable subject within category: *r*	Most reliable subject within category: Subject no.	Most reliable subject within category: *r*	Mean reliability for all subjects
Unpleasant experience						
Emotions	8	28	.24	16	.96	.68
Situations	10	10	−.05	28	.95	.69
Impulses	12	14	.18	20	.95	.66
Behavior	12	2	−.17	25	.97	.60
Pleasant experience						
Emotions	6	12	.13	3	.95	.78

Impulses	7	2	−.15	23	.99	.79
Behavior	7	10	.24	28	1.00	.79

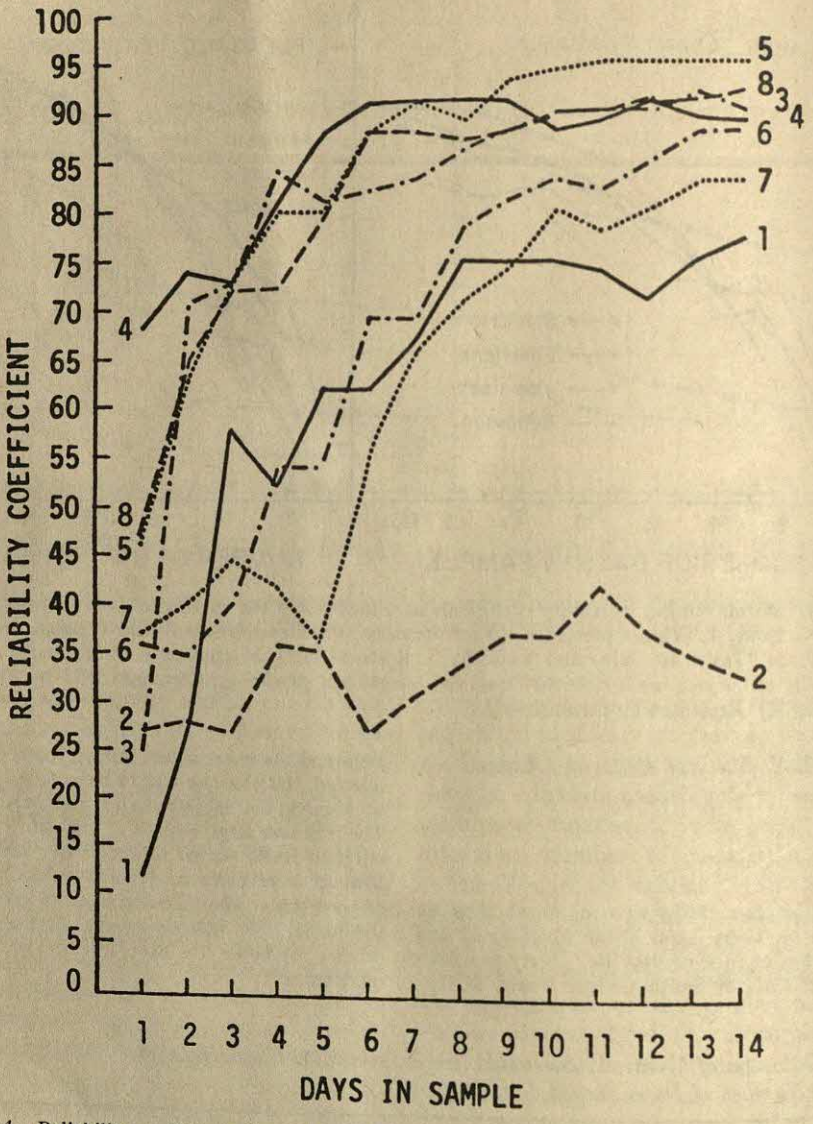

Figure 4. Reliability coefficients for each of the variables in Study 2 as a function of the number of days in the odd–even samples.

Results

As in the previous studies, odd–even correlations were computed for the data averaged over different numbers of days. It can be seen in Figure 4 that for six out of eight variables the pattern is the same, with relatively low reliabilities for a 1-day sample and with increasing reliabilities as the number of observations is increased, until a relatively high level of reliability is obtained. Variable 2, which referred to the closeness of acquaintances with whom a subject initiated conversations and which was a poorly constructed item, since it did not unambiguously define a quantitative continuum, never achieved high reliability, whereas Variable 4, which referred simply to the number of times the subject initiated contacts with others, started with a high reliability coefficient and maintained it throughout.

To determine whether the establishment of a rating set during the course of the study influenced the results, correlations between

the 1st and 2nd day were compared with correlations between the next-to-last and last day. The latter correlations were slightly lower, indicating that the establishment of a rating set during the study could not have contributed to the increase in correlations that occurred with increasing observations.

A further possibility for contamination of the stability coefficients lies in the inferential processes of the observers. That is, a judge's view on stability could have influenced her ratings independent of the behavior of her subject. To the extent that this occurred, it would most clearly be revealed in the ratings of variables that required the most inference. To examine this possibility, variables were sorted into three groups according to the degree of inference required on the part of the observer. It was found that what differences occurred were in the direction of the items which required the least inference producing the highest stability coefficients. Items 3 and 4, which required no inference, produced reliability coefficients of .90 and .89, respectively, which were among the highest obtained (see Figure 4). As demonstrated later, other findings also indicate that the more objective the data, the higher the stability coefficients rise as a function of averaging over observations.

Study 3: Stability of Directly Measured Objective Behavior

Method

This study, in addition to replicating many aspects of Study 1, examined discrete items of objectively measured behavior. It was conducted in two separate classes as an exercise in research.

Nineteen undergraduate seniors in a class in clinical psychology and 15 1st-year graduate students in a class in personality, at the beginning of each class period during the second half of the semester, filled out an adjective checklist on their current emotional state. Following this, they recorded information from daily behavior tallies that they had made since the last meeting. In addition, unknown to the class, the instructor kept records of selected items of behavior.

Current emotional state was rated by the students on 5-point graphic scales anchored at one end with "not at all" and at the other with "very." The scales were identified by clusters of three adjectives, such as happy–cheerful–joyous, the clusters having been determined by factor analysis of adjective checklists used in previous, similar studies (e.g., Epstein, 1976). Ten scales for positive emotions and 10 separate, opposite scales for negative emotions were randomly arranged. In addition to the usual emotions, scales included feelings of self-esteem, arousal, and ability to assimilate information, as these were of special interest for a theory relating emotions to the self-concept (see Epstein, 1973, 1976, in press). After rating their current emotional states, the students transcribed from their daily tally sheets the frequency with which the following occurred since the last class meeting: social telephone calls made and received, social letters written and received, entertainment events attended, and number of headaches and stomach aches. Next, with the instructor keeping time for the class, subjects took three 30-sec samples of their pulse rate and recorded the mean and range. The above information was recorded on computer-scored standard answer sheets. Without the knowledge of the students, the instructor kept records of the following: borrowing of a Number 2 pencil routinely made available to students who had forgotten to bring their own, number of minutes late to class, number of errors and omissions in providing information on the answer sheet, and number of erasures in filling in the spaces for recording answers. In addition, the instructor kept records throughout the semester of number of absences, number of papers turned in late, and number of papers not turned in at all. These will be referred to as fixed variables, as they do not vary over days.

Students in both classes were combined into a single group for the analysis of all variables except minutes late and pencils borrowed, which were recorded only for the undergraduate class. The data finally selected consisted of the records of 15 undergraduates and 11 graduates who had filled out forms properly on at least six Tuesdays and six Thursdays. For all split-half correlations, a balance was maintained between Tuesdays and Thursdays to control for the unequal number of days between meetings.

Results

To evaluate the effects of bias in the self-ratings, it is important to consider that the data can be divided according to level of objectivity in two ways. First, they can be classified as subjective, in the sense that they are descriptions of inner states, and objective, in the sense that they can be observed by an external observer. Second, the latter category can be subdivided according to the degree to which there is the possibility for bias to enter. For example, when a subject records the number of telephone calls or letters he or she has received, the figure may be distorted according to the impression the subject wishes to create. The data can be arranged in three categories of decreasing opportunity for sub-

Table 4
Intercorrelations of Objective Events With Each Other and With Self-Rated Emotions for a 12-Day Sample, and Reliability Coefficients of Objective Events for 1-Day and 12-Day Samples for Study 3

Objective event	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	Emotion

Note. Only correlations of at least .30 are reported. For all variables ($N = 26$) other than pencils forgotten and lateness ($N = 15$), correlations of .39 and .50 are significant respectively at the .05 and .01 levels. For pencils forgotten and lateness, correlations of .51 and .64 are significant at the .05 and .01 levels. Fri = Frightened; A-O = anger-out; A-I = Anger-in; Unh = Unhappy; Fru = Frustrated; Unw = Unworthy; Trd = Tired; Tns = Tense; Pls = Powerless; Cnf = Confused. NA = not applicable; these were fixed variables that consisted of one score for the entire semester.

jective bias as follows: (a) self-recorded events outside the classroom, such as number of telephone calls reported; (b) self-recorded physiological reactions in class, such as the count of pulse rate, with the instructor doing the timing; and (c) examiner-recorded events, such as minutes late to class and number of erasures on the answer sheets. It will be helpful to keep this scheme in mind when examining the influence of bias in self-report on the stability coefficients.

In Table 4, stability coefficients are presented for a 1-day and a 12-day sample for all variables in the study. Also included are the intercorrelations for a 12-day sample of the objective events with each other and with the negative emotions. The results for positive emotions are not included because they add little to the findings for the negative emotions, producing by and large equivalent opposite results. Given a total sample of 12 days, split-half reliability coefficients could, of course, only be computed for subsamples of 6 days. The reliability coefficients for the 12-day sample are estimates obtained by the Spearman-Brown formula for determining the reliability of a total test from the correlation between its halves. To assess the accuracy of such estimates for the current data, 6-day reliability coefficients were estimated from 3-day samples. In all cases, the estimates were almost identical to the values actually observed for a 6-day sample. The 12-day reliability estimates are presented in Table 4, since the intercorrelations of the different variables with each other are all based on 12-day samples, and it is helpful in evaluating the validity coefficients to examine the reliability coefficients for the same number of observations.

All items in Table 4 exhibit a marked increase in reliability from a 1-day to a 12-day sample. For the 12-day sample, 21 of the 23 items have a reliability coefficient of at least .70, and 9 of these are at least .90. Of these 9, only one involves the report of an inner state. The increase in reliability that occurs when data are averaged over events and arranged in order of increasing objectivity results in the following: For the 10 unpleasant inner states, the respective mean coefficients for a 1-day and a 12-day sample are .37 and .77, respectively. For self-recorded behavior that is externally observable, the corresponding figures are .40 and .96. For self-recorded physiological reactions, the corresponding figures are .27 and .94. For examiner-recorded variables, the corresponding figures are .44 and .84. It is noteworthy that all three categories that include externally observable events yield higher reliability coefficients than the category that refers to inner states. That the most objective category, examiner-recorded behavior, attained a somewhat lower level of reliability (.84) than the other two categories of externally observable behavior is attributable to one variable, number of erasures, which had a relatively low frequency of occurrence. The other two variables in this category, lateness and pencils forgotten, obtained reliability coefficients of .94 and .93, respectively. It may be concluded that the increase in reliability as a function of averaging over an increasing number of observations cannot be accounted for by subjective bias associated with self-report, since the same phenomenon was as well demonstrated for objective data. This same conclusion is supported by inspection of Figure 5, which presents the data grouped in a somewhat different fashion. It is apparent in Figure 5 that self-ratings of emotions tend to differ in the direction of producing lower reliability coefficients.

Having established high levels of reliability, let us now examine the data with respect to validity. In Table 4, it is evident that the number of significant correlations of objective events with other objective events and with inner states is well beyond chance. Further, the correlations form coherent patterns. Calls made, calls received, letters written, and letters received are all variables that involve communication with others and are intercorrelated. Erasures, papers missing, and lateness to class, all suggestive of carelessness and lack of organization, are related to the feeling states of tension, powerlessness, and confusion. Heart rate mean, heart rate range, headaches, and stomachaches, suggesting heightened physiological arousal and psychosomatic reactivity, are correlated with unhappiness, confusion, and anger-in but, interestingly, not with anger-out. Heart rate

range, but not heart rate mean, despite the former having a lower reliability coefficient, is significantly correlated with errors (.57) and with erasures (.32), suggesting a variable of physiological lability that is associated with behavioral lability.

It may be concluded that high levels of stability can be demonstrated for objective as well as subjective data when the data are averaged over a sufficient number of events and that once reliability is established, evidence of validity may not be far behind.[2]

Study 4: Relationship of Personality Inventories to Behavior

There are four ways of interpreting the evidence that personality inventories have in the past produced, at best, low correlations when evaluated against a criterion of objective behavior. One is that the two are measuring nonoverlapping aspects of behavior; another is that the inventories are inadequate; a third is that the objective criteria are inadequate; and a fourth is that both are inadequate. Let us consider the possibility that the criteria are inadequate, either because they are unreliable or because they are so narrow and limited in representativeness as to share little variance in common with the broader attributes sampled by personality inventories (see Davidson & Jaccard, 1975; Eagly, 1978; Fishbein & Ajzen, 1974; Jacard, 1974; McGowan & Gormly, 1976; Weigel & Newman, 1976). To the extent that either of these limitations exists, an increase in the sample of objective behavior comprising the criteria should produce an increase in the correlations between personality inventories and objective behavior. Study 4 was undertaken to examine this possibility.

Method

Forty-five undergraduates kept records (on forms similar to those used in the other studies) of their feelings and behavior on 14 consecutive days, not including weekends. Each day, at the same time, a subject set aside 10 min to rate his or her current feelings and to obtain three 30-sec samples of pulse rate. Feelings were rated on bipolar scales with 10 subdivisions that were anchored at one end by a cluster of adjectives, such as happy–cheerful–joyous, and at the other end by an opposite cluster, such as unhappy–sad–depressed. A tally was kept of the following, recorded at the end of each day: number of social phone calls made and received, number of social letters written and received, number of social contacts initiated with groups of three or more people, number of headaches, and number of stomachaches. On the morning of each day, hours of sleep during the previous night were recorded, and a rating was made of soundness of sleep.

Before they began recording their daily behavior, subjects took a battery of personality inventories, including a specific and a general form of a specially constructed inventory made to resemble as closely as possible the forms used for daily recording. The specific form contained precise descriptions of situations and responses. The general form was similar in wording to most standard personality inventories in that it was more vague or general in description of events and response options. An example of an item in the general form is, "How often do you make social phone calls? Consider social calls to include all calls other than business calls." Responses for the general form were selected from a 5-point scale anchored at one end with "almost never" and at the other with "very often." The corresponding item in the specific form was, "How many social phone calls do you make, on the average, over a 5-day period, not including weekends? Consider social calls to include all calls other than business calls." The response options were as follows: less than 1, 1–3, 4–6, 7–9, 10 or more. The general form was always administered before the specific form. Both forms included all the items of objective behavior included in the daily forms, with the exception of heart rate

---

[2] The results are quite different when data from a 1-day sample are examined. A 1-day sample yields a total of eight correlations that are significant at the .05 level when the same variables as in Table 4 are related to each other, as compared to 57 significant relationships when the variables are averaged over 12 days (see Table 4). Moreover, of the eight significant correlations for the 1-day sample, five were produced with the correlation of a fixed variable, papers missing, which is based on the entire semester. The significant correlations for which both variables were based on a 1-day sample were as follows: calls received and calls made (.49), stomachaches and headaches (.58), and unhappy and stomachaches (.39).

To further illustrate the difference between the results for a 1-day and a 12-day sample, consider the interesting, unanticipated findings for heart rate range for a 12-day sample and the absence of any significant relationships for heart rate range when a 1-day sample was examined. In Table 4 it can be seen that for a 12-day sample, heart rate range produced significant correlations with the objective variables of heart rate mean and errors and with self-rated feelings of frustration, unworthiness, and confusion, thereby suggesting an interesting psychosomatic relationship between autonomic lability and behavioral and cognitive lability, a relationship of which there is not a trace in the 1-day sample.

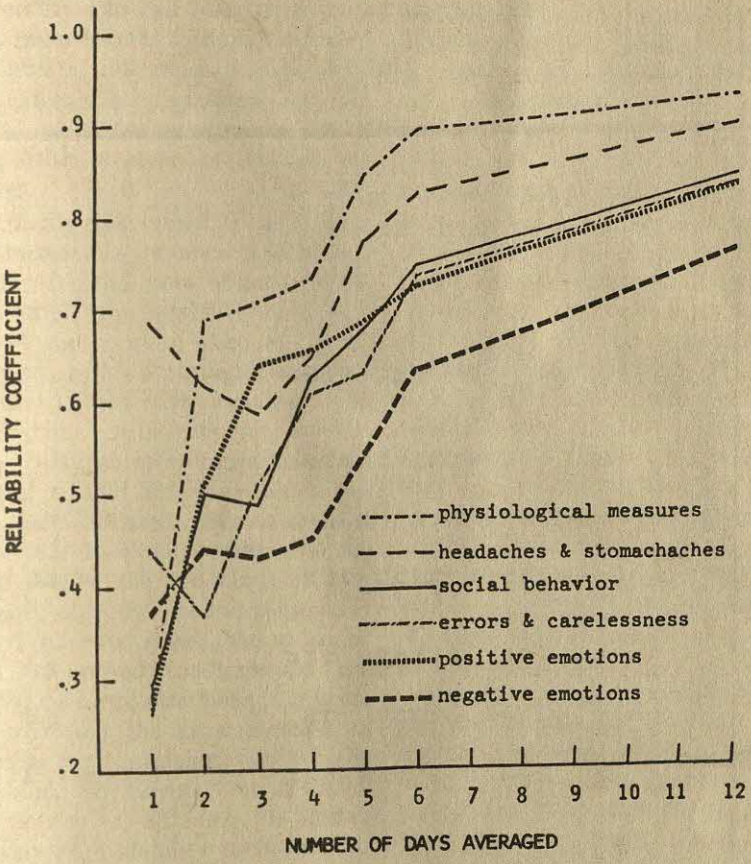

Figure 5. Reliability coefficients as a function of the number of days in the odd–even samples in Study 3. (Values plotted represent the mean of the correlations for the variables in a category. The values for the 12-day samples were estimated from the 6-day samples by the Spearman-Brown formula.)

mean and heart rate range. Frequency of emotions, in the form of an adjective checklist containing single adjectives, was included only in the general form, as it did not seem reasonable to ask subjects to estimate precisely how many times they experienced a particular emotion per day. Subjects responded with estimates of the frequency they experienced the emotions by checking "never," "rarely," "sometimes," "frequently," or "nearly always." Scores on the adjective checklists were obtained by combining individual adjectives into the same 6-item clusters as in the daily forms.

In addition to the above two specially designed inventories, the following more standard personality inventories were administered: the Guilford-Zimmerman Temperament Survey (1949), the Eysenck Personality Inventory (Eysenck & Eysenck, 1968), the Epstein-Fenz Manifest Anxiety scales and the Epstein Hostility scales (Fenz & Epstein, 1965), and the Epstein-O'Brien Self-Esteem Scale (Epstein, 1976). The latter three were specially designed for previous research and have been demonstrated to have some degree of construct validity (cf. Epstein, 1962, 1976; Epstein & Fenz, 1970; Fenz & Epstein, 1965).

Results

The findings on reliability replicate the results of the previous studies that demonstrated a marked rise in stability coefficients as a result of averaging over an increasing number of observations. In Table 5, the stability coefficients for ratings of inner states for a 1-day sample range from .22 for external versus internal direction of attention to .59 for feeling attractive versus unattractive. The mean reliability coefficient for the 15 inner states is .45, which is somewhat higher than in the previous study. The increase in reliability in the present study for a 1-day sample can be attributed to the use of bipolar scales that bring six, rather than three, adjectives to bear on each dimension and that by contrasting the opposites, elucidate the construct. For the entire 14-day sample, as

Table 5

Reliability Coefficients for 1-Day, 7-Day, and 14-Day Samples of Daily Feelings and Events and Correlations of Trait Inventories With 14-Day Samples of Daily Feelings and Objective Events for Study 4

Variable recorded daily	Reliability coefficient			Correlation with scales in trait inventories													
				Trait form of matching scale		Epstein-Fenz anxiety scale			Epstein hostility scale			Epstein-O'Brien self-esteem scale	Guilford-Zimmerman scales				Eysenck scales	
	1-day sample	7-day sample	14-day sample	Specific form	General form	Ins	MT	AA	DH	UH	OH		Res	Asc	Soc	EmS	Ext	Nrt
Emotion																		
Happy–sad	43	66	80		44	−31	−35		−31						36		29	
Kind–angry	55	78	88		48	−43		−29	−40						36	41		−40
Secure–threatened	41	67	80		42	−39	−39	−39	−43	−35	−42							−41
Aroused–tired	32	66	80		45													
Spontaneous–inhibited	41	79	88		40	−36			−31		−30	30		36	41		45	−33

Stomachaches	62	83	91	66	76	31	41	55	49	38						−30		41
M correlation	44	79	88	61	53													33

Note. For bipolar dimensions, positive scores are in the direction of the first term. For standard inventories, only correlations of at least .29 (significant at .05 level) are reported. Correlations of .38 are significant at the .01 level. Decimals are omitted. Ins = Insecurity, MT = Muscle tension, AA = Autonomic arousal, DH = Disturbing hostile feelings, UH = Undercontrolled hostility, OH = Overcontrolled hostility, Res = Restraint, Asc = Ascendance, Soc = Sociability, EmS = Emotional stability, Ext = Extraversion, Nrt = Neuroticism.

estimated from the split-half 7-day coefficients by the Spearman-Brown formula, the reliability coefficients for inner states range from .71 for external versus internal direction of attention to .94 for feeling attractive versus unattractive, with a mean of .86 for the 15 inner states.

A similar increase in reliability as a function of the increase in number of occasions sampled occurs for the more objective data. For a 1-day sample, the reliability coefficients range from .09 for hours of sleep to .70 for heart rate mean, with an average correlation of .44 for the 12 objective variables. The estimated reliability coefficients for a 14-day sample from 7-day samples range from .74 for letters received and letters written to .97 for social contacts initiated, with an average correlation of .88. It is noteworthy that for the objective events, the two kinds of data that were most objective in the sense that they involved nothing more than a count taken under supervised conditions in the classroom, that is, heart rate mean and heart rate range, exhibited the same increase as the other measures, attaining two of the highest reliability coefficients, .94 and .93, respectively. Moreover, although the former had a relatively high stability coefficient for a 1-day sample, the latter did not.

Let us now turn to a consideration of validity by examining the relationships of the personality inventories to the daily recorded events, beginning with the inventories designed to match the daily records on an item-by-item basis. It can be seen in Table 5 that the general form of the inventory has a mean validity coefficient of .53 for objective events, as compared to a validity coefficient of .61 for the specific form. There was apparently a moderate gain in validity as the wording in the self-report inventory was made to more precisely match the criterion. For the specific form, 4 of the 10 validity coefficients are greater than .70, indicating a substantial degree of validity for 40% of the items. These items, with their validity coefficients, are as follows: calls made (.71), calls received (.72), social contacts initiated (.73), and hours of study (.79). Although hours of study requires a degree of inference, as it is not clear exactly what constitutes study, number of letters received and written simply requires a tally of unambiguous events. Thus, the results are not easily explained away by the assumption that daily tallies of events and self-report estimates over an extended period can be viewed as common method variance, in that they both require reports by subjects. Moreover, if all that is involved is common method variance, the correlations of self-report estimates with daily recordings should be as great for a 1-day sample of the latter as for a 14-day sample, which inspection of the data indicates is not the case, and could have been predicted from the consideration that reliability provides a limiting condition for validity. It is noteworthy, in this respect, that in 9 of the 10 variables of objective events under consideration, the validity coefficients for the specific form of the inventory against the criterion of objective events over a 14-day sample are higher than the matching reliability coefficients for a 1-day sample of objective events.[3]

Validity can further be examined by noting the relationships of the standard personality inventories with the 14-day samples of the daily records. It should not be expected, of course, that the relationships will be very high, given the different ranges of generalization encompassed by the recording of specific kinds of behavior and the broad personality dimensions measured by the personality inventories. In Table 5 it can be seen that there are far more significant correlations than would be expected by chance and that the relationships are, for the most part, coherent and relatively high for what is usually obtained for validity coefficients against objective criteria. There is a large number of relationships that break the .30 barrier, and no correlation is in an opposite direction from expectancy. All three of the anxiety scales in the Epstein-Fenz inventory (Fenz & Epstein, 1965) correlate significantly

[3] For a 1-day sample, the mean validity coefficient for self-ratings of emotions was .19 as contrasted with .47 for a 14-day sample. For the general form of the inventory of objective events, the mean validity coefficients for 1-day and 14-day samples were, respectively, .43 and .53. For the specific form of the same inventory, the corresponding figures were .40 and .61.

in the expected direction with daily ratings of threat and tension. Although it is true that the anxiety scales also correlate with daily ratings of other negative feelings, such positive correlations are to be expected, as there is a general tendency for negative emotions to cluster together (see factor analysis of similar data reported in Epstein, 1976). One or more of the anxiety scales correlates significantly negative with soundness of sleep, stomachaches, and headaches. Moreover, the scale of muscle tension correlates more highly with headaches, often a symptom of muscle tension, than with stomachaches, often a symptom of autonomic arousal, whereas the reverse is the case for the scale of autonomic arousal. The scales of overcontrolled hostility and undercontrolled hostility are both directly correlated with daily ratings of threat and of tension, which is reasonable considering that hostility is often a reaction to threat. Yet, only the scale of overcontrolled hostility is significantly correlated with daily ratings of inhibition, inward direction of attention, feelings of helplessness, and lack of reactivity, all of which suggest restraint.

In view of the observation in the previous study that heart rate range is associated with behavioral lability, it is noteworthy that heart rate range in this study is significantly correlated with undercontrolled hostility but not with overcontrolled hostility, whereas heart rate mean is associated with neither. It is of further interest that heart rate range, but not heart rate mean, is significantly associated with the scale of disturbance over hostile feelings (.40) and with Eysenck and Eysenck's (1968) scale of neuroticism (.37), which suggests that, despite its lower reliability than heart rate mean, heart rate range is a more interesting personality variable.

In conformity with the theory of the self-concept (cf. Epstein, 1973, 1976) that guided the selection of the items in the daily forms, the Epstein-O'Brien Self-Esteem Scale (Epstein, 1976) correlates with daily feelings of worthiness (.47), integration (.51), optimism (.55), and alertness (.40). Among the Guilford-Zimmerman scales (1949), the scale of restraint is significantly negatively (−.37), and the scale of sociability significantly positively (.40) associated with number of social contacts initiated. The scale of emotional stability is positively associated with daily ratings of integration (.44), kindliness (.41), optimism (.44), and soundness of sleep (.30) and is negatively associated with frequency of headaches (−.30). The Eysenck (Eysenck & Eysenck, 1968) scale of extraversion is most strongly associated with daily ratings of spontaneity (.45), with outgoing feelings (.47), and with number of social contacts initiated (.52), all of which are recognized elements of extraversion according to Eysenck.[4] The reader may judge for himself or herself by further examination of Table 5 whether the results provide evidence of coherent relationships between self-report inventories and records of daily behavior and feelings.

In summary, the correlations of the daily records with a specific form of an inventory that closely matched the items in the daily form were in the vicinity of .60, the correlations with a more general form of the same inventory were in the vicinity of .50, and the correlations with relevant scales in more standard personality inventories were in the vicinity of .40.[5] It should be noted that all of these correlations are highly significant, that all are above the presumed .30 personality barrier, that none was corrected for attenuation due to unreliability, and that most would be about .10 higher if they were thus corrected. It may be concluded that

---

[4] Not surprisingly, as in the previous study, there were far fewer significant correlations for a 1-day sample, and among these the correlations were lower and less coherent. For example, the Guilford-Zimmerman scale of Sociability (1949) correlated significantly with nine variables, including the variable of number of social contacts initiated, when the data were based on a 14-day sample, but with only one variable when the data were based on a 1-day sample. That variable was self-rated attractiveness, which happens to have relatively high reliability for a 1-day sample (see Table 5).

[5] Similar results have been reported by Zuckerman (1977) and his colleagues (Mellstrom, Cicala, & Zuckerman, 1976; Mellstrom, Zuckerman, & Cicala, 1978; Zuckerman, Note 5). In an interesting series of studies involving inventories, self-rating, and objective measures of fear in a variety of settings, it was observed that the more specifically a trait rating corresponded to a state rating or to an objective measure of behavior, the higher the correlation.

evidence for a respectable degree of validity in self-report inventories can be demonstrated when the criterion consists of an adequate sample of behavior. This is not to imply that scores on personality inventories permit a high degree of accuracy in predicting behavior. The problem of accuracy in predicting behavior will be discussed later.

Discussion

Stability of Behavior and Error of Measurement

The classic debate on stability in personality can be resolved by noting that the problem lay in a failure to take into account error of measurement as it relates to temporal reliability. Single items of behavior, no matter how carefully measured, like single items in a test, normally have too high a component of error of measurement to permit demonstration of high degrees of stability. Once this is recognized, the solution to two related problems becomes apparent. First, the contradictory findings between a few studies that have reported stability in personality using data derived from ratings and a much larger number of studies that failed to find evidence of stability using data derived from the direct measurement of behavior can be accounted for by the observation that the former studies examined adequate samples of behavior, whereas the latter examined single events. Second, the failure to relate self-ratings, ratings by others, and personality inventories to objective behavioral criteria can be accounted for by the unreliability of the behavioral criteria, which almost always consisted of single items of behavior, usually measured in a laboratory setting.

After a review of the literature, the following hypothesis and corollary were formulated: (a) Stability can be demonstrated over a wide range of variables, so long as the behavior in question is averaged over a sufficient number of occurrences. This applies equally to data derived from the direct measurement of objective behavior, from self-reports, and from ratings by others. (b) Significant relationships can be demonstrated between ratings by others and self ratings, including standard personality inventories on the one hand and objective behavior on the other, so long as the objective behavior is sampled over an appropriate level of generality and averaged over a sufficient number of occurrences. Four studies conducted to test the hypothesis and corollary provided unequivocal support for their validity. The studies demonstrated that when single events are examined, there is little evidence for stability, but that when averaging is done over a sufficient sample of events, there is strong evidence for stability, as well as convergence among the different kinds of data. The studies also demonstrated that once high levels of reliability are established, evidence of construct validity is apt to emerge in relationships among the different variables, including ones that do not share common method variance. Thus, error of measurement appears to be the crucial consideration in demonstrating stability in personality and in relating self-ratings and ratings by others to objective data.[6]

It is difficult to believe that with rare exception (e.g., Tryon, 1973), the concept of error of measurement was overlooked throughout the long history of the debate on stability of personality. Perhaps there is a lesson to be learned from this. Can it be that overevaluation of the experimental method, as normally practiced, blinded researchers to the inherent limitations of studying behavior on single occasions? Given the awe in which laboratory experimental procedures have been held, who would have dared to think that they often fail to meet one of the most fundamental scientific tests of all, temporal reliability (replicability)?[7]

---

[6] Other evidence consistent with this thesis is provided by Fishbein and Ajzen (1974), Jacard (1974), Magnusson and Heffler (1969), McGowan and Gormly (1976), Stagner (1977), Tryon (1973), and Weigel and Newman (1976).

[7] To recognize the limitations of the psychological experiment is not to deny its virtues, the primary one of which is to establish causal relationships. Moreover, there are remedies for the limitations. One remedy is to conduct experiments over sessions when this is feasible and appropriate for the phenomenon under consideration, thereby permitting temporal reliability to be assessed and to be increased by averaging over sessions. Another is to encourage replications in different laboratories and to not take

Who would have dared to think that the emperor was wearing no clothing? In both cases the solution is not only emotionally unacceptable but seems too simple to be true. Yet having arrived at the solution, one finds that the future is more hopeful, for delusions can neither warm an emperor nor advance the cause of science. (See also Brunswik, 1947, 1956; Hammond, 1954, 1955; Magnusson & Heffler, 1969; Pervin, 1977; and Tryon, 1973, for other expressions of concern about inadequate sampling of situations.) The broader implications for psychological research of the low temporal reliability of single observations will be discussed in a second article devoted to this topic (Epstein, Note 2).

Issue of Cross-Situational Stability

It has been argued that the real issue with respect to the existence of traits is the demonstration of cross-situational stability. The demonstration of stability per se may, of course, establish nothing more than the existence of narrow habits, which never has been at issue. It is thus important to consider how the findings reported in this article relate to the issue of cross-situational stability.

It will be recalled that a relatively high level of stability in behavior was demonstrated over a wide variety of behaviors, some narrowly conceived, such as making telephone calls, and others broadly conceived, such as feelings of kindliness and acts of nurturance, all of which could be elicited by a variety of situations. Inspection of the data indicated that the same responses were, in fact, elicited by a variety of situations. As the stability that was demonstrated occurred over the normal range of situational variability in everyday life, it would seem fair to state that a meaningful level of cross-situational stability was demonstrated. Expressed otherwise, it was demonstrated that there is enough cross-situational stability in everyday life so that useful statements about individual behavior can be made without having to specify the eliciting situations. This, of course, is the way a trait is usually defined, and the findings demonstrate the utility of such a concept.

Further support for the existence of broad response dispositions was provided by the intercorrelations among the variables. Coherent clusters of correlations occurred not only among variables sharing the same method variance, such as ratings of inner feelings, but also among variables assessed by different methods. Thus, a broadly defined variable in a personality inventory, such as Eysenck's extraversion scale (Eysenck & Eysenck, 1968), produced highly reliable correlations with daily records of feelings of inhibition and of desire for seclusion, as well as with a tally of social contacts initiated, all of which are clearly related to the construct of extraversion as defined by Eysenck. Number of erasures and papers missing, which were recorded by the examiner without the subject's awareness, not only correlated reliably with each other but correlated reliably with daily self-reports of feelings of tension, powerlessness, and confusion.

The conclusion that there are relatively broad, stable response dispositions, or traits, does not conflict with the assumption that situations often exert a strong influence on behavior. People obviously do not manifest response dispositions independent of the setting. That is why it is usually necessary to cancel out situational effects, including subtle background effects that often go unrecognized, by averaging over occasions to demonstrate stability in behavior. By the same token, demonstrations that behavior varies with situations cannot be taken as evidence against traits. The fact that people read in a library and swim in a swimming pool does not establish that there is no generality, or "cross-situational stability," in either swimming or in reading behavior. More to the point is that some people are more prone to

---

any finding seriously until it has been replicated on several occasions. Undoubtedly there are some experimental situations that produce temporally reliable results on a single occasion, whereas others require averaging over occasions. The former very likely include highly potent, ego-involving variables as well as certain very simple effects. However, which situations actually produce temporally reliable results on single occasions cannot simply be assumed, but must be established by empirical procedures in which the temporal reliability of the psychological experiment itself is the object of investigation. This matter is further pursued in Epstein (Note 2).

swim than others when there is a reasonable opportunity to do so, and this may include swimming in pools, in lakes, and in oceans. Further, one cannot test such a cross-situational proclivity to swim by observing a person once in the vicinity of a swimming pool and once in the vicinity of a lake, as there may be many reasons for that person to forego swimming on a particular occasion. Behavior is obviously determined by more than response dispositions. Given an adequate sample of occasions, however, response dispositions will out.

Issue of Predictability of Behavior

How stable is stable? It has been demonstrated that there is sufficient stability in behavior so that over a sufficient sample of events, threads of consistency become apparent. As noted above, in any one instance behavior is determined largely by the situation. This, of course, allows one to predict situational effects averaged over subjects but not necessarily an individual's rank order, as represented by a correlation coefficient, from one situation to the next.

It is important to recognize that no situation for an individual can ever exactly reproduce another, if only because the time lag in between must have somewhat changed the individual, including his or her momentary motivational state. Moreover, always behaving in the same way in the same situation without regard to contextual changes would be behaving in a pathologically rigid manner. On the basis of such considerations alone, it should not have been surprising that the correlations between single items of behavior on different occasions are usually below .30.

To predict individual behavior with reasonable accuracy, correlations in the vicinity of .80 or .90 are required. In the four studies reported in this article, correlations of such magnitude were obtained when the average of a sample of 14 days was correlated with the average of another sample of 14 days, but rarely for smaller samples of behavior. This indicates that one can predict average behavior accurately from a similar sample of average behavior. However, the prediction is only actuarial and is a far cry from predicting with confidence to individual instances of behavior. How useful is such actuarial prediction? It is extremely useful, for it tells us that in the long run, we can depend on people behaving true to character. As I have noted elsewhere (Epstein, 1977), whether we are betting our finances on the outcome of material events or betting our happiness on the outcome of human relationships, it can be extremely rewarding to be right more often than allowed for by chance. From such a perspective, even correlations much lower than .80 or .90 can be useful.[8] With this in mind, let us examine the correlations of self-report statements with daily behavior.

When self-report items that were highly specific in wording were compared with corresponding objective criteria, correlations in the vicinity of .60 were obtained. When the self-report items were worded in a more diffuse manner, the correlations fell to about .50. When standard personality inventories were used that defined much broader styles of functioning than the behavioral criteria to which they were compared, the correlations were, on the average, about .40, but several were above .50. Although none of these allows great accuracy in prediction, all allow much better than chance prediction from information that is readily obtained. Moreover, there is reason to believe that these correlations could be improved by including equally broad categories of items in both the criterion sample and the self-report measure (see studies by the Blocks [in Block, 1977] and by Hartshorne & May, 1928, 1929, described in this paper; see also Fishbein & Ajzen, 1974). It remains to be determined how high such correlations can be brought when a broad sample of matching behavior for the two sets of variables is obtained, and this is combined with averaging the criterion over a sufficient number of occasions to bring it to as high a level of temporal reliability as is customarily

[8] Any correlation that is significantly greater than zero can, of course, be useful for theoretical purposes. In fact, it would be inefficient to have to develop methods and measures that permitted high degrees of prediction to test theories, particularly in early stages of theory development in which it is often desirable to explore many variables, both dependent and independent, rather than pursue a few in depth.

obtained for personality inventories. If both measures had sufficiently high stability coefficients, then at least the unreliability of the criterion would not be a limiting factor for validity, as it customarily has been.

Finally, it should be noted that not everyone is equally predictable. This was demonstrated in the present article by the finding that within-subject correlations varied over a range that suggested almost no stability in a few individuals and extremely high stability in others, with most individuals demonstrating a moderately high degree of stability. Bem and Allen (1974) observed that a sample of subjects who described themselves as highly consistent produced moderately high stability coefficients, whereas a sample of subjects who reported they were not consistent produced low coefficients. The authors concluded that stability in personality can be demonstrated only for specially selected samples of subjects, which is aptly reflected in their title, "On Predicting Some of the People Some of the Time." According to our findings, it is not necessary to select particular classes of people to demonstrate stability unless one has failed to obtain a sufficient sample of behavior to begin with, in which case one needs individuals with unusually high stability to compensate for a high degree of error of measurement. As demonstrated in the present article, given an adequate sample of behavior to begin with, it should be possible "to predict most of the people much of the time."

Psychological Differentiation: Current Status

Herman A. Witkin, Donald R. Goodenough, and Philip K. Oltman
Educational Testing Service, Princeton, New Jersey

The status of the differentiation hypothesis, derived from differentiation theory, is examined in light of the evidence that has accumulated since the hypothesis was proposed a decade and a half ago. Assuming that greater or less differentiation is an organismic attribute, the hypothesis postulates that behaviors reflecting extent of differentiation are likely to be interrelated, resulting in self-consistency in individual functioning across domains. The newer evidence has, on the whole, confirmed the linkages among the behaviors examined in the earlier research that was done to test the differentiation hypothesis. The differentiation hypothesis has also proven useful in generating predictions about linkages to behaviors in new domains (cognitive restructuring, interpersonal competencies, and cerebral lateralization); these predictions have been tested and generally confirmed. The differentiation construct appears able to account for phenomena that cannot be accommodated by other lower order constructs, such as field dependence–independence. On all these grounds the differentiation construct continues to serve a useful function. Whereas the differentiation hypothesis has dealt only with the interrelatedness among components of a cluster of behaviors subsumed under differentiation, the newer evidence carries suggestions for a hierarchical ordering of these components and for the nature of causal connections among them.

The differentiation construct was introduced into the stream of research on field dependence–independence in 1962 to accommodate new findings and to guide further research on the broad patterns of psychological functioning associated with individual differences in manner of establishing the upright in space (Witkin, Dyk, Faterson, Goodenough, & Karp, 1962/1974).

Briefly stated, differentiation is a major formal property of an organismic system. A less differentiated system is in a relatively homogeneous state; a more differentiated system is in a relatively heterogeneous state. A system that is more differentiated shows greater self–nonself segregation, signifying definite boundaries between an inner core of attributes, feelings, and needs identified as the self, and the outer world, particularly other people. In a less differentiated system, in contrast, there is greater connectedness between self and others. A system that is more differentiated is also characterized by greater segregation of psychological functions; that is, functions are more separate from each other and activities within each are more specialized.[1]

To make the differentiation construct a useful guide for research, it was necessary to operationalize it by specifying the particular ways in which greater or less differentiation

Herman A. Witkin died on July 8, 1979, while this article was in press.

The preparation of this review was aided by Grant MH-21989 from NIMH.

[1] Although more differentiated systems are likely to be more complexly organized (i.e., relationships among system components and between the system and its environment are more elaborate), there is no inherent relation between differentiation and effectiveness of integration (i.e., the harmonious working together of system components with each other, and of the system as a whole with its environment). Supporting the concept that level of differentiation is unrelated to effectiveness of integration are the results of many studies that have shown that more differentiated and less differentiated people are not different in sheer presence or absence of psychopathology, in other words, in being well adjusted or poorly adjusted (Witkin, 1965).

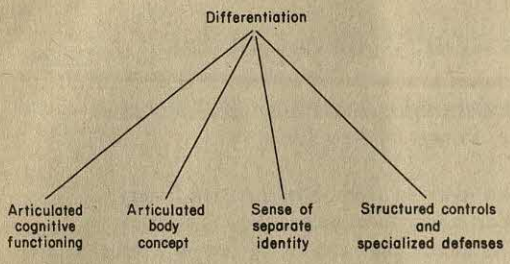

Figure 1. 1962 model of differentiation.

may show itself in different psychological domains, and by formulating testable hypotheses. Assuming that the development of differentiation is an organismwide process, the main hypothesis we proposed was that greater or less differentiation is likely to be characteristic of an individual's activities in diverse domains. According to this differentiation hypothesis, functional manifestations or indicators of greater or less differentiation should be related to some extent, resulting in self-consistency in functioning across domains. We held this expectation, though recognizing that special training and experience during growth may contribute to unequal progress among areas, and that dedifferentiation during aging or with psychological impairment may affect functioning irregularly from one area to another.

In the theoretical conception that guided our research, shown schematically in Figure 1, differentiation was considered a high-order individual-differences construct, with four lower order constructs radiating from it. The first of these was articulated cognitive functioning. To experience parts of organized fields as discrete and to organize unstructured fields, which articulation implies, is to show differentiation in the cognitive domain. The second was an articulated body concept. This refers to an impression of the body as having definite limits or boundaries, and the parts within as discrete yet interrelated and joined into a definite structure. The third was sense of separate identity—that is, identification of attributes, needs, and values that are recognized as one's own and as distinct from those of others. The availability of an internal core of characteristics and standards was expected to enable the person to function with relatively little need for guidance and support from others, and to maintain an internally derived perspective in the face of contradictory perspectives of others. The fourth was availability of structured controls over impulse expression and the use of specialized defenses for dealing with potentially disturbing experiences. Both signify more differentiated functioning, in contrast to the diffuse expression of impulse and the use of nonspecific defenses. By 1962 there was a good deal of evidence that measures of these lower order constructs were interrelated, as hypothesized.

Since then, the differentiation hypothesis has been the stimulus for a large body of further research.[2] A segment of that research, concerned with the field-dependence–independence cognitive-style component of differentiation, has recently been reviewed elsewhere (Witkin & Goodenough, in press; Witkin & Goodenough, Note 5). Our main task here is the broader one of examining the differentiation hypothesis in light of the newer evidence. We consider that evidence under the headings of the four lower order constructs of the 1962 model of differentiation.

Articulated Versus Global Field Approach

The articulated verus global concept emerged from a line of research on individual differences in perceptual and intellectual functioning that began with studies of perception of the upright in the rod-and-frame test (RFT), body-adjustment test (BAT), and rotating-room test (RRT). In each of these tests, subjects differed in the extent to which they used the external visual field or the body itself as the main referent for locating the upright; and they were self-consistent across tests in their tendency to rely primarily on the one referent or the other. These contrasting tendencies were designated *field dependent and field independent.*

Later, manner of locating the upright was shown to be related to relative ease of separating part of an organized field from the field as a whole, as in the embedded-figures test (EFT), in which the task is to find a simple

[2] For recent comprehensive bibliographies see Cox and Witkin (Note 1); Witkin, Cox, and Friedman (Note 2); Witkin, Cox, Friedman, Hrishikesan, and Siegel (Note 3); Witkin et al., (Note 4).

figure within a complex design (Witkin et al., 1954/1972). Since the requirement of separating the item from its embedding context in this task appeared similar to the task of keeping a rod or the body apart from the surrounding field in the RFT, BAT, and RRT, we redefined the field-dependence–independence concept as a disembedding ability in perception. Disembedding ability in perception was subsequently related to disembedding ability in intellectual activities, and disembedding ability in both domains was related to structuring competence in both domains. To analyze and structure fields is to show articulated cognitive functioning as a characteristic approach to the field; to follow the field as given is to use a global approach. This greatly enlarged individual-differences dimension was conceived as an articulated versus global field approach dimension, and was designated a cognitive style.

Since 1962, a great deal of research has been carried out on the articulated–global field approach conception. (See Witkin & Goodenough, in press, and Witkin & Goodenough, Note 5, for recent reviews of that research.) This research has confirmed the picture of self-consistency in cognitive functioning established earlier, and extended it by linking a wide array of spatial–visual cognitive dimensions to field dependence–independence in perception of the upright. A common feature of situations in which these dimensions are represented is that the person has to restructure percepts or symbolic representations to meet the requirements of the task. Field-independent people are better able to accomplish such restructuring, in contrast to field-dependent people who are more likely to follow the prevailing organization of a stimulus array as given. Examples of restructuring acts on which people who are field-independent in perception of the upright do better are locating a simple figure in a complex organized gestalt (as in the EFT; e.g., Goodenough & Karp, 1961), achieving alternative perspectives in spatial–visualization tasks (e.g., Gardner, Jackson, & Messick, 1960; Gough & Olton, 1972), showing conservation in Piagetian situations (e.g., Pascual-Leone, 1969), and breaking a set in Einstellung problems (e.g., Busse, 1968; Dinius, 1975). Most factor-analytic studies have suggested that the restructuring competence related to field independence in perception of the upright may be limited to performance on spatial–visualization types of tasks, but the evidence on the issue is not conclusive.

Recent research on the articulated–global field approach concept also suggests that manner of mixing visual and vestibular information, rather than cognitive restructuring (Witkin & Goodenough, in press; Witkin & Goodenough, Note 5), may underlie individual differences in performance on tests of perception of the upright. In a later section of this article, we consider alternatives to the disembedding hypothesis that may account for the relation that exists between manner of establishing the upright and performance in cognitive restructuring tasks such as the EFT.

Articulated Body Concept

People's conception of their bodies is the product of bringing into a coherent entity a wide array of experiences while growing up. These experiences have their primary sources in children's apprehension of their bodies through vision; in the tactile and kinesthetic feedback arising from their manual exploration of their bodies and from their motoric and bodily functions; and in the handling of their bodies by other people. The bodies of others provide still another source of experience. The typical progression in development of the body concept is from a relatively global view of the body, to awareness of its constituent parts and their interrelatedness, as well as awareness of the outer limits of the body. The outcome of this progression is an articulated body concept —that is, one in which components of the body are experienced as discrete and joined into a bounded whole. According to the differentiation hypothesis, individual differences in position on the articulated–global body-concept dimension should be related to differences in position on the field-dependence–independence cognitive-style dimension.[3] This expectation

[3] The differentiation hypothesis supposes that measures of the postulated indicators of extent of differentiation would tend to be related to each other. In the studies described in our earlier report (Witkin et al., 1962/1974), intercorrelations among measures of these indicators were examined and were generally found to be significant. Reflecting the early and continuing role of

was confirmed in our early studies, in which we used an articulation of body concept scale, applied to human figure drawings, to assess that aspect of the body concept (Faterson & Witkin, 1970; Witkin et al., 1962/1974). This relationship has been further confirmed with a high degree of consistency in many subsequent studies (e.g., Adevai, Silverman, & McGough, 1968; Pizzamiglio & Carli, 1973; Schuck, Cross, & Mills, 1970; Winestine, 1969).

Some studies have examined articulation of body concept by means other than figure drawings. One set of studies used the Finger Apposition Test (Jacobson, 1944), which requires subjects to reproduce with their own hands the finger positions of pairs of hands shown in a series of photographs. The ability to manipulate the hands vicariously in imagination, to achieve a particular relationship between them, was conceived to require an articulated conception of one's own body. A similar kind of reasoning lay behind the use of the Laterality Orientation Test (Culver, 1969) and the Hands Test (Thurstone, 1938) in another set of studies. In these tests the subject is required to identify the sidedness of drawings of right or left body parts. Most studies found the expected relationship between scores on these tests and measures of field dependence–independence (Adams, 1974; Adevai et al., 1968; Bachelis, 1965; Culver, Cohen, Silverman, & Shmavonian, 1964; Epstein, 1961; Gaughran, 1964).

Still other studies considered only the body-boundary component of an articulated body concept. Some of these used the "barrier index" (Fisher & Cleveland, 1958), an indirect indicator of body-concept boundaries based on frequency of bounded percepts in a subject's Rorschach productions. Although a few studies found a relation between boundary scores and field independence (Jacobson, 1965; analyses by Fisher of data from Young, 1959, cited in Witkin et al., 1962/1974), most have not (e.g., Bachelis, 1965; Carlson, Tucker, Harrow, & Quinlan, 1971; Siegel, 1977). Other studies came closer to the body itself in their assessment of body-boundary characteristics, by examining discreteness of experiences on the surface of the body through such indicators as the two-point threshold, traced letter identification, and tactile localization (Adams, 1974; Adevai et al., 1968; Bachelis, 1965; Cohen, Silverman, & Shmavonian, 1962; Paquette, 1974; Silverman, Cohen, Shmavonian, & Greenberg, 1961). In most instances, the anticipated relationship was found between field independence and the measures of discreteness of experience on the surface of the body.

If the various measures derived from tasks involving the body itself do indeed allow inferences about articulation of body concept, we have, in these studies, a suggestion that the relationship between field dependence–independence and that body-concept dimension is not method specific, in the sense of being limited to the figure-drawing, articulation-of-body-concept assessment technique. Additional studies using more experimental approaches to examination of the body concept are clearly needed, however.

Sense of Separate Identity

The extensive evidence derived from studies carried out since 1962 under the aegis of the sense of separate identity concept, recently reviewed by Witkin and Goodenough (1977), has essentially confirmed and extended past findings.

In one approach, sense of separate identity was assessed through its expression in self-object differentiation. Winestine (1969) used strength of the twinning reaction, as an indication of standing on that dimension, for each member of the pairs of male twins she studied. The twinning reaction was conceived to be stronger the greater the degree of interidentification of the boy with his twin, as assessed from an interview with the boy. Boys with a stronger twinning reaction were significantly

---

perception of the upright and perceptual disembedding in our research, as well as the availability of effective tests of these functions, it has predominantly been relations between performance on the RFT and/or EFT and measures of each of the other indicators that have been examined in the subsequent research on differentiation, reviewed in this and the following sections of this article. Although there is some additional evidence on relations among measures of the other indicators in the more recent literature, that evidence is limited and is not considered here.

more field dependent. Olesker (1978), following the separation–individualization model of Mahler (Mahler, 1966; Mahler, Pine, & Bergman, 1975), assessed degree of self–object differentiation through extended observations of young children in a nursery school. Again, greater self–object differentiation was significantly related to greater field independence. Baraga (1978), also working within the Mahler framework, found that less attachment at age 1 was associated with greater field independence at age 3, although the expected relations between field dependence–independence and particular maternal characteristics and child behaviors were not found. Finally, Paul (1975) observed that children who showed difficulty in separating from parents after 1 week of nursery school experience were more field dependent than children who did not.

Another body of evidence has demonstrated that people who show greater autonomy of the external visual field in perception of the upright also tend to function more autonomously of others in social-interpersonal situations, particularly under conditions of ambiguity (e.g., Shulman, 1976; Solar, Davenport, & Bruehl, 1969; Weinberg, 1970). This finding broadens the picture of self-consistency in functioning across domains in ways consistent with the differentiation hypothesis.

The evidence linking autonomy in perception of the upright to autonomy of external referents in social behavior has affected our usage of the cognitive-style and field-dependence–independence concepts (Witkin & Goodenough, in press; Witkin & Goodenough, Note 5). We now apply the designation *cognitive style* to the contrasting tendencies to rely primarily on external referents or on the self in psychological functioning.[4] We have also transferred the designation *field dependence–independence* to this process dimension from its early use as a label for disembedding ability in perception.

Another important product of the more recent research on sense of separate identity is its demonstration that field-dependent people tend to have an interpersonal orientation and field-independent people an impersonal orientation (Witkin & Goodenough, 1977). Compared to field-independent people, field-dependent ones favor social over solitary situations (e.g., Coates, Lord, & Jakabovics, 1975; Crandall & Sinkeldam, 1964; Nadeau, 1969); they prefer to be physically close to others in an interaction situation (Greene, 1976; Justice, 1970; Wineman, 1974); they are selectively attentive to social sources of information (e.g., Fitz, 1971; Fitzgibbons, Goldberger, & Eagle, 1965; Konstadt & Forman, 1965); they are open in expressing their feelings and thoughts (DeMers, 1971; Greene, 1976; Sousa-Poza & Rohrberg, 1976), an approach likely to elicit similar behavior from others toward them. These attributes and behaviors seem likely to provide the person with information about what others may be feeling and thinking, as well as experience in dealing with people. They may thereby facilitate getting along with others. Probably contributing to that same end are such characteristics ascribed to field-dependent people as considerate and attentive to others (e.g., Elliott, 1961). Indeed, evidence is beginning to emerge that field-dependent people may be more effective in social interactions than more field-independent people (e.g., Oltman, Goodenough, Witkin, Freedman, & Friedman, 1975). The social attributes and behaviors useful in interpersonal relations, found among field-dependent people, and their apparently greater facility in getting along with others add up to a picture of interpersonal competencies.

Research on the social skills associated with field dependence–independence is limited, reflecting the relatively recent emergence of interest in the social domain in the history of work on psychological differentiation. More precise specification of the interpersonal competencies characteristic of relatively field-dependent people and of the social skills com-

---

[4] Other dimensions that on the surface may appear similar to field dependence–independence in fact are not. An example is the locus-of-control construct. This dimension is conceptually different from the field-dependence–independence dimension, and many studies have shown, almost invariably, that measures of the two dimensions are not related (e.g., Roodin, Broughton, & Vaught, 1974; Shapson, 1973; Tobacyk, Broughton, & Vaught, 1975). Field dependence–independence is conceived as a process variable, representing degree of autonomy of external referents in processing information from field and self; locus of control is a belief or attitudinal variable, representing greater or less fatalism as an outlook on life.

mon among more field-independent people,[5] as well as a clearer conceptualization of these competencies and skills within the differentiation framework, are tasks that lie ahead.

The involvement of cognitive restructuring skills and interpersonal competencies in field dependence–independence makes that cognitive-style dimension bipolar, in the sense of having no clear high and low ends: People at the field-independent pole have more developed cognitive restructuring skills, and people at the field-dependent pole are more likely to give evidence of interpersonal competencies. To the extent that at both poles we find characteristics adaptive in particular situations, the field-dependence–independence cognitive-style dimension is not value biased.

Segregation of Psychological Functions

The main trademark of segregation of psychological functions, a major manifestation of differentiation, is specificity of activities and experiences. Signifying the development of specificity are the formation of structured controls for routing impulses and expending energy and the formation of specialized defenses for dealing with potentially disturbing experiences. The differentiation hypothesis leads us to expect that these indicators of greater differentiation would be related to field independence.

With regard to controls, early in life, impulses are likely to find expression in diffuse systemwide reactions. As the child grows older, structured systems of control are developed that make possible the specific channeling of impulse. This accomplishment diminishes the likelihood of a "spilling over" of the content of one domain into another, thereby avoiding the too easy mixing of the ideational, affective, motivational, and motoric.

With regard to defenses, some may be considered relatively unspecialized, in the sense that they involve dealing with experience in a global fashion. Examples are denial and repression, which are characterized by a turning away from perception of the content of an immediate experience, or the memory of a past experience, often in its entirety. In the case of denial, the existence of a disturbing external reality as a whole may not be acknowledged. Repression, when used as a generalized defensive strategy, has been conceived in psychoanalytic theory to be the blocking from awareness of not only objectionable instinctual demands but the impulses, thoughts, and feelings associated with them as well. In contrast to these nonspecific ways of functioning, defenses such as isolation, intellectualization, and projection are more specialized. These defenses are characteristically directed at particular components of experience, which may be obliterated or made more pallid, or they may act to separate components of experience that are actually connected, without the components necessarily being lost. In the case of isolation, the connections between ideas and feelings (or wishes or impulses) that are actually related are lost from awareness, although the affect and ideation are consciously available to the person. Intellectualization is a defense in which affect is neglected or excluded, whereas the ideational components of the experience remain in force. Even though its affective content is washed out, the experience continues to be available to the person in its intellectual aspects as something that can be named and defined. Finally, in projection, specific characteristics and purposes are attributed to the person who is its object; it is thus not indiscriminate in its action.

To the extent that structured controls signify specialization of functions and contribute to specificity of behavior, we may expect from the differentiation hypothesis that field-independent people will provide more evidence of the availability and use of struc-

---

[5] Very little is yet known about the social skills to be found among field-independent people, beyond the fact that such people tend to be limited in interpersonal competencies. Some of these people, who have been described as aloof, distant, and solitary, are likely to stay away from interpersonal involvement as much as possible. There are indications that when field-independent people do invest in the social sphere, their social skills may in fact be expressions of their restructuring abilities, taking the form of ordering and organizing social situations, perspectivism, and accuracy in the more cognitive aspects of person perception resulting from use of an analytical approach. These skills would appear to contrast with those more common among field-dependent people that particularly involve facility in getting along with others. The evidence on these points is hardly conclusive, but it suggests directions for the research that is needed.

tured controls, compared to field-dependent people. The characteristics of specialization and specificity of defenses, such as intellectualization, isolation, and projection, would similarly lead us to expect these defenses to be more commonly used by field-independent people, and the use of more global defenses, such as repression and denial, to be more common among field-dependent people.

Structured Controls

In one set of studies, degree of structure of controls was inferred from the content of a battery of projective tests or from particular projective test responses reflecting directness of affective discharge, with controls judged to be more structured when the expression of affect was modulated or mediated (Freedman & Marks, 1965; Gardner, Holzman, Klein, Linton, & Spence, 1959; Guskin, 1955; Witkin et al., 1962/1974; Witkin et al., 1954/1972). Most of these clinical studies found the expected tendency for field-independent subjects to show more structured controls, although the evidence is not entirely consistent. In line with these findings is the observation (Witkin, Lewis, & Weil, 1968) that field-dependent patients showed more diffuse anxiety in their verbal productions during psychotherapy when these productions were assessed according to the Gottschalk-Gleser method (Gottschalk & Gleser, 1969), although these two kinds of patients were not different in overall amount of anxiety expressed.

Other studies have assessed structure of controls from observations of behavior. Crutchfield and Starkweather (Note 6) found that judges described field-dependent adults they had observed over a period of time as people who "undercontrol impulses" and "act with insufficient thinking and deliberateness." Performance on the mazes task has been observed for the evidence it provides of impulsivity versus control in carrying out a specific activity. In most studies, field-dependent subjects, both children and adults, were more likely to provide evidence of impulsive behavior than were field-independent subjects (e.g., Best, 1975; Gorman, 1968; Podell & Phillips, 1959; Swan, 1974). A related set of studies was concerned with motoric inhibition. The method used required the subject to carry out a well-practiced act—such as drawing a line, walking a line, or writing one's own name—very slowly. Many studies with children have shown capacity for motor inhibition to be greater among field-independent than field-dependent children (e.g., Eddy, 1974; Maccoby, Dowley, Hagen, & Degerman, 1965; Mayer, 1967; Mumbauer & Miller, 1970). Other studies with children did not find a relation between field dependence–independence and assessments of impulse control from general behavior manifestations (Reppucci, 1970; Seitz, 1972) or from behavior manifestations together with psychological test data (Gardner & Moriarty, 1968). On the other hand, with a high degree of consistency, hyperactive children, in whom impulsivity is a prominent characteristic, have proved to be field dependent (e.g., Campbell, Douglas, & Morgenstern, 1971; Cohen, Weiss, & Minde, 1972; Douglas, 1972; Halverson & Waldrop, 1976).

Measures of impulsivity from self-report inventories have generally proved not to be related to field dependence–independence. This outcome may be a function of particular characteristics of these inventories.[6]

---

[6] Self-report inventory measures of defenses generally do not relate to field dependence–independence either. The possibility that the contrast between the results from self-report inventories and the results obtained with projective test responses and behavioral observations may be a function of the methodologies involved is supported by several observations made in other areas of research on psychological differentiation. As one illustration, mothers' reports of their actual behavior with their children tend to distinguish significantly between the child-rearing experiences of relatively field-dependent and field-independent children, but mothers' expressed attitudes toward child rearing generally do not (Witkin & Goodenough, in press; Goodenough & Witkin, Note 7). As another example, studies of the position subjects assume in relation to those with whom they are interacting have shown that field-dependent people prefer to be closer to others than do field-independent people; on the other hand, subjects' responses to hypothetical situations involving the use of interpersonal space have not shown such a difference (Witkin & Goodenough, 1977). As still another example, whereas field-dependent people are more responsive to group standards when the standard is derived from actual interaction with a group, no difference has typically been found between field-dependent and field-independent people when the standard was given in the form of a statement attributed to either an authoritative source or a bogus group average (Witkin

By most signs, field-independent people thus give evidence of greater regulation of affective discharge and of motor activities, suggesting the presence of more structured controls.

Specialized Defenses

The nature of the defenses predominantly used by field-dependent and field-independent people has been examined in many studies employing a variety of approaches.

In one approach, clinical assessments of defenses were made. The clinical techniques used have included the Rorschach (e.g., Bertini, 1962; Levine & Spivak, 1964; Morrison & Centers, 1969; Schimek, 1968); an interview (Witkin et al., 1954, 1972) or therapy interactions (Safer, 1975); a battery of psychological tests and behavioral observations (Gardner & Moriarty, 1968); Blacky Pictures and the Sentence Completion Test (Lutzky & Schmeidler, 1963; Silverstone, 1966); and the Defense Mechanism Inventory, developed by Gleser and Ihilevich (1969) (e.g., Bogo, Winget, & Gleser, 1970; Donovan, Hague, & O'Leary, 1975; Erickson, Smyth, Donovan, & O'Leary, 1976; Williamson, 1977). In another kind of study, repressors and isolators were identified through performance on a metacontrast situation (Almgren, 1971; Nilsson & Almgren, 1970). The weight of the evidence from these studies together is that field-independent people are prone to use isolation, intellectualization, and projection as characteristic defenses, whereas field-dependent people are more likely to use repression and denial.

Evidence relevant to the issue of defenses has also come from studies of the effects of stress on recall and perception. These studies have shown that field-dependent people, compared to field-independent ones, are more likely to forget previously learned stressful material than neutral material (e.g., Duvall, 1970; Rosen, 1963; Schimek & Wachtel, 1969; Uhlmann & Saltz, 1965). Field-dependent people have also been shown to be more affected by stressful material in perception (e.g., Almgren, 1971; Duvall, 1970; Lefcourt, Gronnerud, & McDonald, 1973; Minard & Mooney, 1969).

Still another kind of evidence comes from the literature on dream forgetting, a phenomenon that has been attributed to repression. This evidence, recently reviewed by Goodenough (1976), suggests that people who characteristically fail to recall their dreams, particularly stressful ones, are likely to be field dependent.

The expectation from the differentiation hypothesis that field-independent people are more prone to use specialized defenses, such as isolation, intellectualization, and projection,[7] and field-dependent people to use less specialized defenses, such as repression and denial, has received substantial confirmation from the available evidence.[8]

Further Evidence on "Keeping Things Separate"

Greater discreteness of functions and experiences, signifying segregation and specialization of activities, has been observed among field-

& Goodenough, 1977). It appears that the most consistent relations are found between field dependence–independence and a variety of personality and social variables when assessment of these variables is made under conditions in which subjects interact with others and in which actual behavior is used as the basis of assessment. Relations are less likely to be found when hypothetical situations or attitudes are the media of assessment. To the extent that self-report inventories include items of these kinds, their predictive value in relation to field dependence–independence may be diminished.

[7] The use of more specialized defenses has the general consequence of separating the self from emotions by reducing the potency of affect, giving ascendancy to the more cognitive aspects of experience. There is an evident parallel between this emphasis on the cognitive side of psychic life among field-independent people and their impersonal orientation, with its emphasis on ideas and abstract principle. Thus, field-independent people have been characterized as highly cathecting intellectual activities (Crutchfield, Woodworth, & Albrecht, 1958.)

[8] The use of more specialized or less specialized defenses carries no implication as to effectiveness of adjustment. Thus, the use of intellectualization may be a valuable aid in the development of the individual's intellectual potential, by giving intellectual processes freedom from intrusion of feelings, impulses, and wishes that may divert these processes and impair their effectiveness. Extreme reliance on intellectualization, however, may hamper the development of the individual's emotional life. Similarly, repression may help the individual to function unhampered by threatening feelings and memories that if allowed entry into awareness, could be disruptive; extreme reliance on repression may constrict development of salient parts of the personality.

independent people in psychological domains other than controls and defenses.

One illustration comes from a study by Brilhart (1970) that examined the influence of affective features of a communication on subjects' evaluations of its cognitive content. Two messages were prepared on a given theme; one was "good" in its cognitive structure and content, the other "poor." In addition, each kind of message was delivered by a good or poor speaker. Among field-dependent subjects, but not among field-independent ones, estimates of the logic of the message were influenced by the kind of speaker who delivered it. Thus, field-independent subjects, more than field-dependent ones, kept cognitive features of the message separate from the personal context in which it was presented.

A quite different kind of evidence on the maintenance of discreteness may be found in the domain of stimulus generalization. A recent review (Goodenough, 1976) indicates that generalization along a stimulus continuum is less among field-independent than among field-dependent people. Thus, field-independent people more quickly attach the critical response to a particular stimulus in the array, inhibiting expression of that response to other stimuli.

The evidence reviewed here is, on the whole, consistent with expectations from the differentiation hypothesis, that greater field independence is likely to be associated with greater specialization of psychological functions.

Neurophysiological Differentiation

On the premise that differentiation is a broad organismic construct, we may expect greater or less differentiation to manifest itself in the neurophysiological domain as well as in the psychological domain. It is only recently that the rapidly expanding knowledge about asymmetrical specialization of the hemispheres of the brain has made it possible to formulate explicit hypotheses, within differentiation theory, regarding linkages between psychological and neurophysiological differentiation (Oltman, Note 8).

A great deal of evidence now indicates that among normal right-handed people, the left and right hemispheres have characteristically different modes of processing information (e.g., Dimond & Beaumont, 1974; Milner, 1975). The left hemisphere, served most directly by the right visual field and right ear, seems particularly suited to the processing of verbal-conceptual and executive motor functions. The mode of functioning of the right hemisphere, served most directly by the left visual field and left ear, has been characterized in ways that imply holistic processing of configurations or gestalten (e.g., Bogen, 1975). These observations lend themselves to interpretation within the differentiation framework. Specialization of the functions of the two hemispheres may be taken as an indicator of neurophysiological differentiation, much as specialization has served as an indicator of psychological differentiation. The differentiation hypothesis leads us to predict that greater specialization in the psychological domain will be linked to greater specialization in the neurophysiological domain. In particular, we may expect that field-independent people, compared to field-dependent ones, will show evidence of greater lateral specialization of the hemispheres; this will show itself in greater specialization of the left hemisphere for verbal and motor control processing, and greater specialization of the right hemisphere for configurational-gestalt processing. The emphasis, it should be noted, is on degree of lateralization of different types of processing in the respective sides, not on the dominance of one hemisphere over the other as a generalized hemisphericity tendency.

Evidence of the linkages between psychological and neurophysiological differentiation, as predicted by differentiation theory, is now available from a number of studies using a variety of approaches.

It is a well-established observation that in right-handed individuals the perception of faces is processed primarily by the right hemisphere (e.g., Hilliard, 1973; Rizzolatti, Umiltà, & Berlucchi, 1971). Using a composite face-perception technique (Gilbert & Bakan, 1973), Oltman, Ehrlichman, and Cox (1977) found a significant tendency for relatively field-independent subjects to show a stronger left visual field bias than did field-dependent subjects. Thus, when confronted with a task

that is more suited to the processing mode of the right hemisphere, the field-independent observers gave particular weight to cues from the left visual field, which project most directly to the right hemisphere. Field-dependent subjects showed little or no lateralization on this task.

Complementing the Oltman et al. (1977) study of right-hemisphere functions are studies of left-hemisphere functions. One such study, by Sousa-Poza and Rohrberg (Note 9), took as its point of departure the observation by Kimura (1973) that right-handed speakers typically make most of their speech-related gestures with their right hands. Sousa-Poza and Rohrberg found that this relationship was moderated by field dependence–independence, however. Although relatively field-independent speakers gestured primarily with their right hands, conforming to the modal pattern described by Kimura, field-dependent speakers showed more bilateral speech-related gestures.

The Kimura (1973) finding apparently reflects left-hemisphere control, in general, of both speech and speech-related right-hand movements. On this basis, the relatively greater number of bilateral speech-related movements among field-dependent people may reflect a more bilateral representation of language. Results consistent with the idea of more definite left-hemisphere language representation among field-independent people have come from studies using the dichotic listening technique. Those studies show that persons with stronger right-ear superiority in the processing of verbal material tend to be relatively field independent (Dawson, 1977; Pizzamiglio, 1974; Pizzamiglio & Cecchini, 1971; Waber, 1977b).

Assessments of extent of lateralization of left-hemisphere and right-hemisphere processing, as a function of field dependence–independence, were recently combined in a single study (Zoccolotti & Oltman, 1978). Rizzolatti et al. (1971) had earlier found that overall, discrimination reaction times were faster to letters when they were presented tachistoscopically to the right visual field (which projects directly to the left "verbal hemisphere"), and were faster to faces shown in the left visual field (which projects directly to the right "configurational hemisphere"). Using the same stimuli employed by Rizzolatti et al., Zoccolot and Oltman found this pattern of opposi visual-field superiorities, as a function of t type of processing required, among their fiel independent, but not among their field-d pendent, subjects. These two kinds of subje were not different in overall performance either task. A recent study by Rapaczyns and Ehrlichman (Note 10), using a face recog tion task, found reversed, rather than small hemifield differences in their field-depende subjects, but the complexity of the task th used and the less accurate overall performanc of their field-dependent subjects make int pretation of these results difficult.[9]

In addition to leading to differences in b havior of the kinds considered, differentiati of function of the two hemispheres may also expected to show itself more directly in diff ences in electrical activity of the hemispher The more similar the activities in the two hem spheres (or the less different their function the more similar are the electroencephalogra (EEG) recordings from the left and rig hemispheres likely to be. Oltman, Semple, a Goldstein (in press) recently found th fluctuations over time, in integrated EE amplitudes, showed significantly higher c relations between left and right hemispher among field-dependent subjects.

Still another kind of evidence, of a mo indirect nature, comes from studies of su groups that differ in degree of lateralization well as in performance on tests of field pendence–independence or on tests of spati visualization ability, one of the cognitive structuring dimensions in which field inc pendence expresses itself. For example, seve studies have shown that women tend to be l strongly lateralized than men (e.g., Kimu

---

[9] In the face-recognition data of Rapaczynski a Ehrlichman (Note 10), the field-independent subje showed the usual left-visual-field superiority, but fie dependent subjects showed a significant right-fi superiority. The task used required a verbal report o fixation digit in addition to face recognition, and fie dependent subjects showed lower overall performa on the face task. The combination of a verbal report a face discrimination in the same series of trials com cates inferences about extent of lateralization in processing of the face stimuli, particularly since level of performance also differed between the grou

1969; McGlone & Davidson, 1973; Ray, Morell, Frediani, & Tucker, 1976), and there is considerable evidence that people who are not fully right-handed are less lateralized than those who are clearly right-handed (e.g., Gilbert & Bakan, 1973; Silverman, Adevai, & McGough, 1966; Zangwill, 1960). As to the cognitive style of these less lateralized groups, women are relatively more field dependent than men (e.g., Witkin et al., 1962/1974), and they do less well on spatial tests (e.g., Maccoby & Jacklin, 1974). Similarly, people who are less than fully right-handed are relatively more field dependent than clear right-handers (e.g., Dawson, 1977; Pizzamiglio, 1974; Silverman et al., 1966), and they tend to be lower in spatial ability (Levy, 1969; Miller, 1971), although the evidence on this point is not entirely consistent (e.g., Briggs, Nebes, & Kinsbourne, 1976). The indications that women and non-right-handers are less lateralized, and relatively field dependent as well, are consistent with the proposal from the differentiation hypothesis that degree of lateralization is related to standing on the field-dependence–independence dimension.

In all, the evidence that greater neurophysiological differentiation tends to be associated with a more field-independent cognitive style lends support to the differentiation hypothesis.

Theoretical Implications

We assume that level of differentiation is a broad organismic dimension. On that basis, we have hypothesized that the tendency to function in more differentiated or less differentiated fashion is likely to be evident, to some degree, throughout an individual's psychological and neurophysiological activities. This expectation of self-consistency has received considerable support in the evidence that has been reviewed. The manifestations of greater or less differentiation found to be interrelated are quite diverse, and together cover considerable psychological and neurophysiological territory.

Beyond confirming the linkages among functions and behaviors identified in the earlier work, the newer research has shown that the differentiation hypothesis meets the requirement of any useful conception, that it be able to generate testable predictions in new domains. Now implicated in the differentiation network, through that research, are such additional domains as cerebral lateralization, cognitive restructuring, and interpersonal behavior. The differentiation construct also seems able to account for findings and relationships that cannot be accounted for by other constructs in our conceptual framework. Thus, the field-dependence–independence construct, now defined as extent of autonomous functioning, is not able to accommodate such phenomena as nature of controls and defenses or extent of cerebral lateralization, whereas the broader differentiation construct can do so.

The differentiation hypothesis is essentially a proposal to account for an association, among components of a network of functions and behaviors, responsible for a particular kind of individual self-consistency. It does not concern itself with the issue of hierarchical ordering of the components; nor does it concern itself with the issue of causal influences of the components on each other, either in the person's current functioning or during development. The issues of hierarchical ordering and of causal interconnections have recently come to the fore, stimulated in part by the addition of new areas to the differentiation network.

A hierarchical ordering primarily signifies an arrangement of constructs from more general to more specific; it may carry the implication as well that higher order constructs influence lower order ones. In our 1962 model (Figure 1), differentiation was the most general construct, and the series of postulated indicators of extent of differentiation constituted an array of narrower, lower order constructs, all of equal status. From the more recent research, proposals have emerged for amalgamating some of the lower order constructs, as well as proposals for a larger number of delineated constructs varying in degree of specificity. A plausible structure incorporating these proposals is shown in its main outlines in Figure 2 and is discussed later along with some elaborations and possible alternatives. As in our earlier model, differentiation continues to be located at the apex. At the level immediately below the apex are the three major indicators of differentiation: self–nonself segregation, segre-

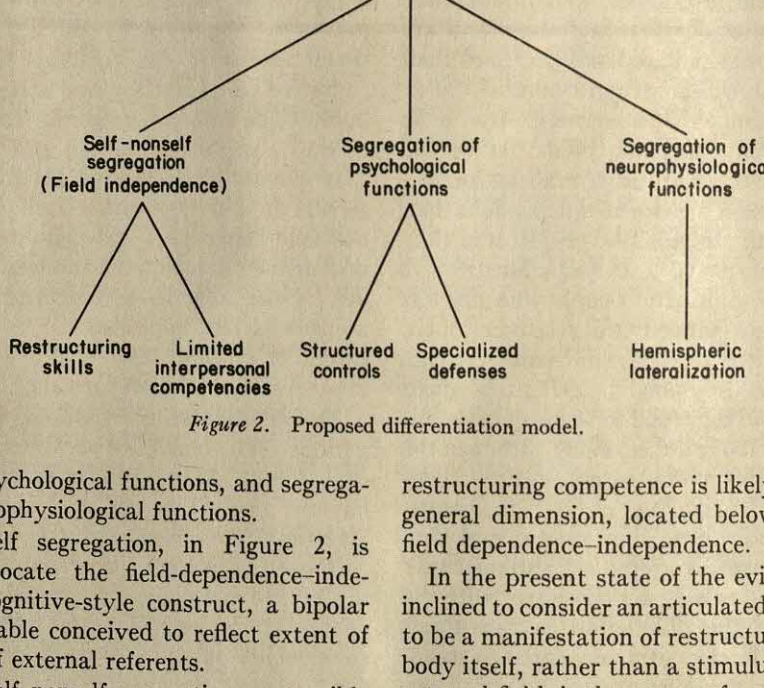

Figure 2. Proposed differentiation model.

gation of psychological functions, and segregation of neurophysiological functions.

Self–nonself segregation, in Figure 2, is where we locate the field-dependence–independence cognitive-style construct, a bipolar process variable conceived to reflect extent of autonomy of external referents.

Limited self–nonself segregation, responsible for less autonomous functioning or a field-dependent cognitive style, signifies continued connectedness with others. Such connectedness, it seems reasonable to postulate, fosters the development of an interpersonal orientation, "fellow feeling," a fund of knowledge about others, and facility in getting along with others—in other words, interpersonal competencies. Interpersonal competencies are, in this view, a derivative of greater connectedness with others, and hence a construct below the level of self–nonself segregation or field dependence–independence.

It also seems possible that cognitive-restructuring abilities may be a product of field independence. Whether a person tends to rely primarily on external referents or to be self-reliant might be expected to influence the development of cognitive-restructuring skills. A person who functions less autonomously may adhere to a percept or symbolic representation as given when dealing with restructuring tasks. A more autonomously functioning person may go beyond the information given when that is required by situational demands or inner needs. If this view of the relationship between autonomy and restructuring is correct, then restructuring competence is likely to be a ve general dimension, located below the level field dependence–independence.

In the present state of the evidence, we a inclined to consider an articulated body conce to be a manifestation of restructuring when t body itself, rather than a stimulus array in t external field, is the source of experience, as the examples of restructuring consider earlier. Articulation emphasizes the mo cognitive aspects of the body concept, and pa ticularly the person's view of the spatial repr sentation of the body. Though formation the body concept is a process that takes pla over the course of development, it may be se to entail the imposition of structure on stimulus array much as do some of the pro lem-solving tasks we considered, which call f structuring at the moment they are carried ou In suggesting that an articulated body co cept be subsumed under cognitive restructu ing, we are changing the location of that co struct from the higher order status it had our earlier model in Figure 1.

Consistent with the concept that extent autonomy may exert a causal influence on t development of interpersonal competencies an restructuring skills is the evidence from a larg body of cross-cultural research (e.g., Witki 1978; Witkin & Berry, 1975; Witkin et a 1974). It appears that societies that encourag autonomy from societal and parental authorit in young children, in comparison to societie that stress conformity, tend to produce peopl who show the associated characteristics

field independence in perception of the upright, competence in cognitive restructuring, and self-reliance. The contrasting set of characteristics is more common in societies that encourage conformity. Extent of socialization for autonomy is thus implicated as central to the development of this cluster of characteristics.

We have proposed that the greater self–nonself polarity and more autonomous functioning of field-independent people may foster the development of cognitive restructuring skills among them, but it is not as likely to foster the development of interpersonal competencies. We have also proposed that the greater recourse of field-dependent people to external referents stimulates the development of interpersonal competencies, but may be responsible for these people's lesser cognitive restructuring skills. Relatively field-dependent and field-independent people may thus be seen as making their main developmental investment in different domains, with the result that their psychological development proceeds along different pathways. This conception views the development of differentiation as multilinear; genuine development takes place along both the pathways of limited differentiation and greater differentiation. This conception also implies that cognitive styles, which are process variables, influence the development of patterns of abilities—cognitive restructuring skills and interpersonal competencies—and so may be regarded as expressing themselves in these abilities.

The second major indicator of differentiation, segregation of psychological functions, is manifested in other ways, in structured controls and specialized defenses. These manifestations thus have the status of more specific constructs below the level of segregation of psychological functions.

The third major indicator of differentiation, segregation of neurophysiological functions, is located at the same level in our model as the psychological indicators, segregation of psychological functions and self–nonself segregation. Below the level of neurophysiological segregation we place the construct lateralization of cerebral functions, in which neurophysiological segregation manifests itself.

Within the differentiation framework, segregation of neurophysiological functions may provide causal pathways to the development of the psychological manifestations of differentiation, in addition to the socialization and experiential pathways that have been suggested at various points. (To avoid undue complexity, these pathways are not shown in Figure 2.) Psychological functions are rooted in a substratum of neurophysiological activity; therefore, specialization of functions at a neurophysiological level may be an important determinant of specialization of psychological functions. The possible influence of neurophysiological specialization on the development of cognitive restructuring and of specialized defenses may be examined as illustrative.

With regard to cognitive restructuring, one might suppose that the processing modes that are characteristic of the left and right hemispheres are maximally effective if they are localized in separate hemispheres. Levy (1969, 1974) has proposed that when language representation is bilateral, verbal functions will predominate at the expense of configurational-gestalt processes. It may be, as Teuber (1975) has suggested, that speech is established earlier and is more resilient, thereby attaining a favored position wherever it is located. That is, extent of hemispheric specialization may have little effect on verbal competence, but it is likely to facilitate spatial-configurational processes ordinarily mediated by the right hemisphere, either alone or in complex interaction with the left hemisphere's propositional mode. Although the scope of the cognitive-restructuring dimension has not yet been conclusively established, the weight of the evidence currently available suggests that the cognitive correlates of field independence in perception of the upright may be limited to spatial-visual restructuring abilities. If this suggestion is confirmed by future research, Levy's hypothesis may help to explain such a possible limitation, and individual differences in spatial-restructuring abilities may be understood as a consequence, in part, of degree of cerebral lateralization.[10]

---

[10] Waber (1977a), working within the framework of Levy's (1969) hypothesis, has recently proposed a model that implicates hormonal factors. There is evidence, although it is not entirely consistent, that individuals of both sexes who reach puberty relatively

Turning to the possible influence of cerebral specialization on specialization of defenses, we have proposed that greater differentiation manifests itself in clear separation between affect and ideas or percepts. This separation may perhaps be related to the newly emerging evidence that the right hemisphere, in addition to mediating spatial-configurational processes, may also be implicated in the expression and control of affect (Carmon & Nachshon, 1973; Gainotti, 1972; Galin, 1974; Heilman, Scholes, & Watson, 1975; Schwartz, Davidson, & Maer, 1975). If there is a special role for the right hemisphere in affective experience and expression, we might then ask whether greater or less cerebral lateralization may enter into determining how affect and ideation are interrelated. It is perhaps possible that one of the bases for the relative lack of separation of feelings and ideas among less differentiated people is a neural organization in which parts of the brain ordinarily involved in their processing are not as specialized for these purposes. Such a possibility seems consistent with the differentiation framework and is capable of generating testable predictions.

The possible involvement of cerebral specialization in the psychological components of the differentiation cluster suggests that causal influences may cross the three main pathways radiating from differentiation, in the model sketched in Figure 2, making for multidetermination of these components. In still broader perspective, it may well be that the socialization practices that encourage self–nonself segregation and individual autonomy (see Witkin & Goodenough, in press, and Goodenough & Witkin, Note 7, for recent reviews) have much in common with those that encourage the development of such expressions of segregation of psychological functions as structured controls and specialized defenses (Dyk, 1969; Dyk & Witkin, 1965; Witkin et al., 1962/1974). Moreover, socialization practices may well influence the development of neurophysiological differentiation, which in turn may have its own consequences for a variety of specific psychological functions implicated in the differentiation framework. That socialization experiences may indeed affect the development of lateralization is suggested by the finding of Kimura (1967) and Geffner and Hochberg (1971) that their lower socioeconomic status (SES) children developed the usual right-ear advantage in dichotic listening later than did middle and upper SES children. Although we do not yet know the precise nature of the operative variables involved, or their overlap with the socialization variables implicated in the development of self–nonself segregation and segregation of psychological functions, it seems that experience may be one important source of individual differences in neurophysiological differentiation.

Complementing these various routes of causal influence are possibilities for more directly acting causal effects. Thus, training has been shown to enhance specific restructuring skills such as disembedding (Witkin & Goodenough, in press; Goodenough, & Witkin, Note 7), and it may affect restructuring as a general competence as well (Dolecki, 1976). The development of interpersonal competencies is, of course, also subject to direct influence by appropriate social experiences.

Much progress has been made over the years in elaborating and making more specific the propositions of differentiation theory and enlarging its empirical underpinning. With this expansion have come new questions that now require answers, an inevitable accompaniment of the evolution of any theory. The varied directions for further work that have been opened by recent research on differentiation theory provide an encouraging sign of the theory's continuing usefulness.

early tend to be less lateralized and less competent in cognitive restructuring, although not different in verbal functioning, as compared to late maturers (e.g., Broverman, Broverman, Vogel, Palmer, & Klaiber, 1964; Petersen, 1976; Waber, 1977b). Waber suggests that the relationship between pubertal age and restructuring ability is mediated by hormonal influences on the development of hemispheric specialization.

Self As Actor, Active Observer, and Passive Observer: Implications for Causal Attributions

John D. Cunningham

Southern California

David E. Kanouse
Rand Corporation
Santa Monica, California

Miller and Norman have distinguished between active observers (those on the receiving end of an actor's behavior) and passive observers (onlookers of an event involving an actor and an active observer). Following the concept of hedonic relevance, it was hypothesized that active observers will attribute the actor's behavior to personal dispositions of the actor even more strongly than passive observers will. In a series of hypothetical emotional events, subjects were depicted either as actors ("You like Ted"), active observers ("Ted likes you"), or passive observers ("Ted likes Paul"). They then rated the degree to which the actor, active observer, or some "other reason" had caused the given event. Although the actor–observer effect was obtained overall, an interaction between subject role and positivity of verb indicated that it occurred much more strongly in negative-verb events than in positive-verb events. That is, subjects—as either actors or active observers—tended to deny their responsibility for negative events but did not claim praise for positive events. Implications for the effects of egotism on attribution are discussed.

The intriguingly simple hypothesis of Jones and Nisbett (1971) that "there is a pervasive tendency for actors to attribute their actions to situational requirements, whereas observers tend to attribute the same actions to personal dispositions" (p. 2) has sparked a profusion of research in recent years. In any interpersonal situation that involves both actors and observers, it is necessary to distinguish between two types of observers, active and passive. Miller and Norman (1975) stated that

> the term *active observer* refers to any participant in a social interaction situation who, in addition to observing the behavior of the other participants, influences the behavior of the other participants and is himself behaviorally influenced by the other participants. Active observers, therefore, function as both actors and observers. The term *passive observer* . . . refers to an individual who neither influences nor is influenced by the actor he is observing. (p. 503)

Clearly, this distinction is critical, since the active observer's attributions are more likely to be swayed than the passive observer's by the hedonic relevance and personalism of the actor's behavior (Chaikin & Cooper, 1973; Hill & Jones, 1973; Jones & Davis, 1965).

Among all of the interpersonal studies to be found in the actor–observer literature, few have investigated this distinction explicitly (Miller & Norman, 1975; Wolfson & Salancik, 1977; Weber, 1975; Cunningham & Antill, Note 1). Miller and Norman found, as predicted, that active observers attributed more behavioral responsibility to the actor and less responsibility to the interaction setting—a Prisoner's Dilemma game—than passive observers did. Supportive of Miller and Norman's results, divergent attributions were produced

Thanks are due John H. Harvey and two anonymous reviewers for their perceptive comments on a previous draft of this article.

by actors and active observers in two other bargaining studies (Snyder, Stephan, & Rosenfield, 1976; Stephan, Rosenfield, & Stephan, 1976). Yet Wolfson and Salancik's (1977) "involved (i.e., active) observers," who watched an actor operate a model race car set while anticipating competing against either the actor or another subject, made more situational (external) and fewer dispositional (internal) attributions for the actor's failing performance than uninvolved (passive) observers. To the extent that both involved and noncompetitive observers' attributions paralleled those of actors, these observers seemed to have adopted an empathic set (Regan & Totten, 1975; Stephan, 1975) rather than the motivationally defensive posture of the bargaining game players. The emergence of either empathic or "egotistic" (Snyder et al., 1976) attribution thus seems to be a complex function of the patterning of interaction (trial-by-trial bargaining vs. observer role anticipating actor role), outcome (success–failure vs. no explicit result), and sex of subjects. Unfortunately, the unstructured-conversation paradigm of Cunningham and Antill (Note 1) and Weber (1975)—the only apparent active–passive observer studies that did not use a competitive or achievement setting—yielded no differences between the attributions of active and passive observers.

The present study was conducted in the hope that a simplified paradigm would bring clarity to the issue of similarity or divergence in attributions made by actors, active observers, and passive observers. Jones and Nisbett (1971) have argued that both informational bias and information-processing bias contribute to differences in attributions made by actors and observers. The studies by Miller and Norman (1975) and by Wolfson and Salancik (1977) differed, among other ways, in the amount of information available to the active observer; in the latter study, the actor performed in full view of the active observer, but in the former, he was never seen. Regan and Totten (1975) showed that through induction of an empathic set, information processing alone can yield actor–observer differences. In a questionnaire format, the present study sought to minimize informational complexity but permit information-processing differences by locating the actor as the subject of a sentence ("You like Paul") and the active observer as the object of a sentence ("Ted likes you").

Using success and failure at hypothetical achievement events, Ruble (1973) manipulated actor–observer perspective by phrasing sentence subjects in the third person for the passive-observer role (e.g., "John Doe didn't work well with others on a project"), as opposed to the second person for the actor role (e.g., "You worked well with others on a project"). Incorporating these actor and passive-observer roles, this procedure was adapted in the present study to include the active-observer role as well by phrasing certain sentence objects in the second person (e.g., "Ted likes you"). Emotional verbs were used particularly to determine whether the predominance of causal attributions to sentence objects for subjective verbs in passive-observer events (Abelson & Kanouse, 1966; McArthur, 1972) would shift to sentence subjects in active-observer events, as the results of Miller and Norman (1975) would predict.

A second goal of the study examined the effect of extremity of event on ascriptions of causality. More extreme or severe consequences lead observers to assign greater responsibility to actors (Cunningham & Kelley, 1975; Walster, 1966), whereas actors attribute less responsibility and freedom to themselves (Harvey, Harris, & Barnes, 1975). It is predicted that actors and active observers will place the locus of causality for extreme emotional reactions more in the other person than in themselves, whereas passive observers will attribute greater causality to sentence subjects as emotions become more extreme.

Method

Subjects

Subjects were 24 male undergraduates at the University of California, Los Angeles, who participated in partial fulfillment of an introductory psychology course requirement.

Materials

A series of one-sentence interpersonal events depicting subjective emotional states was constructed (e.g.,

"Ted likes Paul somewhat"). Sentence subjects and objects were either common male first names or the pronoun *you*. Actor–observer perspective was manipulated by four combinations of subject–object pairings, for example, "Ted . . . Paul," "Paul . . . Ted," "You . . . Paul" (self as actor), and "Paul . . . you" (self as active observer). Four positive–negative verb pairs were used (like–dislike, admire–resent, love–hate, and trust–distrust). All verbs were phrased in the present tense. The extremity or intensity of the event was varied by the inclusion of a moderate ("somewhat") or extreme ("deeply") modifier. The complete crossing of all possible combinations of these four variables—actor–observer role, verb, positivity, and extremity—yielded a total of 64 events.

Each event was followed by three one-sentence causes or explanations for the given event. The first cause referred to qualities of the sentence subject, and the second referred to qualities of the sentence object. The third attribution ("some other reason") was left optional for experimental subjects to rate. Subjects were told to "rate each of these explanations on how likely it is that they caused the initial situation," and to make their rating of each cause independent of their ratings of the other causes. A typical item follows:

Ted likes Paul somewhat.
How likely is this because:

A. Ted is the kind of person that likes people.

1 2 3 4 5 6 7 8 9

B. Paul is the kind of person that people like.

1 2 3 4 5 6 7 8 9

C. Some other reason

1 2 3 4 5 6 7 8 9

The 9-point Likert scales were anchored at each end by "not likely" or "definitely likely" and at the midpoint by "moderately likely."

All subjects made ratings for all 64 events. However, all events containing the pronoun *you* were grouped in one booklet of 32 events, and all events with first names only were grouped in another booklet of 32 events. Within each booklet, the sequence of events was randomized, but each subject received the same sequence of events. The order in which subjects received one booklet or the other first was the only between-subjects variable.

Results

As preliminary analyses indicated that no significant differences appeared between pairs of equivalent passive-observer statements (e.g., "Ted likes Paul" and "Paul likes Ted"), these data were pooled in subsequent analyses so that the subject-role variable had three levels: actor, active observer, and passive observer.[1] All ratings were subjected to multivariate analysis of variance (Dixon, 197 Harris, 1975) with order of presentation booklet as the only between-subjects variab and with subject role, positivity, extremity, a verbs as repeated measures. The depende variables were the ratings of sentence acto active observers, and "other reasons" causes of the given event.

Order of Presentation Effects

The multivariate effects involving order presentation of booklets are sporadic a difficult to interpret. Also, no significant mai effect or interaction involving order emerge when the three dependent variables we analyzed separately. But when all three d pendent variables were taken together—i the multivariate analysis—subjects who r ceived the booklet containing passive-observe events first rated causality for negative-ver events lower than positive events and lowe than subjects who received that bookle second, Order × Positivity interaction, $F($ 196) = 32.7, $p < .001$. Those who receive the booklet containing passive-observer event first gave lower ratings of causality for event for which self "loves" or "hates" someon else than all of the other combinations, Orde × Verb × Subject Role multivariate inte action, $F(27, 573.06) = 3.19$, $p < .001$.[2] Thos who received the self-relevant booklet fir rated moderate negative events involvi self as actor or active observer highes whereas those receiving the other bookl first rated extreme negative events involvi self as actor or active observer highest, Orde × Positivity × Extremity × Subject Ro multivariate interaction, $F(9, 477.16) = 3.4$ $p < .001$. However, none of these order effect changed the conclusions to be drawn fro the other results, nor did they correspond

[1] Pooling of the equivalent passive-observer sta ments resulted in twice as many observations in passive-observer condition as in either the actor active-observer conditions. Unequal cell sizes w accommodated by the BMD computer program us in the analyses (Dixon, 1973).

[2] Fractional degrees of freedom appear because the algorithm employed by the program to deal wi unequal cell sizes (Dixon, 1973).

any apparent way to effects obtained when the order of actor and observer roles was manipulated (Sherrod & Farber, 1975, in failure situations).

Actor–Observer Hypothesis and Hedonic Relevance

A significant multivariate main effect for subject role lends support to the actor–observer hypothesis, as attributions to the self either as actor or as active observer were lowest of all means, $F(9, 477.16) = 67.9$, $p < .001$. When this analysis was performed on ratings of actor and active observer only on events that involved the self (i.e., actor role and active-observer role), the subject-role main effect emerged even more strongly, $F(6, 392) = 100.6$, $p < .001$. This confirms Miller and Norman's (1975) distinction between active and passive observers to the extent that subjects attributed less causality to themselves as active observers than when others were portrayed as active observers.

However, the Jones–Nisbett (1971) effect was ancillary to an interaction between subject role and positivity that reflected the hedonic relevance of the event. That is, subjects were much more reluctant to attribute causality to the self for negative verbs (e.g., hate and distrust) than for positive verbs, multivariate $F(9, 477.16) = 26.7$, $p < .001$. Indeed, an orthogonal comparison pitting negative verb-event ratings of self as actor and of self as active observer against the other 16 means in this interaction was highly significant, $F(1, 23) = 64.0$, $p < .001$. Thus, contrary to Miller and Norman's findings, the active observer did not attribute greater causality to the actor than a passive observer did. Rather, the active observer attributed—in negative events predominantly—less causality to self, as active observer, than a passive observer did.

Following the significant multivariate interaction between subject role and positivity, univariate interactions appeared for causal attributions to active and active observer separately, $F(3, 42) = 5.30$ and 8.96, ps $< .005$ and .001, respectively. As can be seen in Table 1, subjects tended to deny responsibility for negative events when they were cast either as actors or as active observers. Orthogonal comparisons probing these interactions showed that negative verb ratings of self as actor were much lower than all other actor ratings, $F(1, 23) = 29.7$, $p < .001$, and that negative verb ratings of self as active observer were much lower than all other active-observer ratings, $F(1, 23) = 46.8$, $p < .001$. On the other hand, positive verb ratings of self as actor were only somewhat lower than all other actor ratings, $F(1, 23) = 4.98$, $p < .04$, and positive verb ratings of self as active observer did not differ from all other active-observer ratings ($F < 1$).

Table 1
Mean Causal Attributions to Actor and Active Observer As a Function of Subject Role and Verb Positivity

Causal attribution to	Subject role: Actor	Active observer	Passive observer
Actor			
Positive verb	4.67	5.33	5.29
Negative verb	3.53	5.14	5.17
Active observer			
Positive verb	5.48	5.81	6.12
Negative verb	4.97	3.81	5.33

Note. A sample sentence in the actor condition is "You like Ted"; in the active observer condition is "Ted likes you"; and in the passive observer condition is "Ted likes Paul."

Verb Effects and Extremity Effects

The interaction between actor–observer perspective and positivity was particularly pronounced on events involving the verb *hate* and nearly as pronounced on the verb *dislike*, multivariate interaction, $F(27, 573.06) = 2.78$, $p < .001$. As a consequence, negative verbs, such as dislike and hate, received the lowest causality ratings of all verbs, and positive verbs, especially trust, the highest, multivariate interaction, $F(9, 477.16) = 8.95$, $p < .001$. Positive verbs had higher ratings than negative verbs on actor and active-observer ratings, univariate $F(1, 14) = 23.2$ and 34.5, respectively, both ps $< .001$, but lower ratings on other reasons, $F(1, 14) = 10.3$, $p < .01$. As predicted, more causality was attributed to actors for extremely negative events than for

moderately positive events, as seen in the significant multivariate interaction between extremity and positivity, $F(3, 196) = 4.07$, $p < .01$. Overall, extreme events were rated higher on causality ratings than moderate events, $F(3, 196) = 10.8$, $p < .001$; this was particularly true of other reasons ratings.

Discussion

The main conclusion to be drawn from this study is that the actor–observer hypothesis of Jones and Nisbett (1971) may hold true particularly for blameworthy or socially undesirable events, that is, events involving hatred, distrust, dislike, or resentment. Whenever portrayed as a participant in such an event, as either an actor or an active observer, the subject deflected blame from the self, directing it instead to the other person or to some unspecified other reason. This did not occur to the same extent when the subject was depicted as either an actor or active observer in a socially desirable event, that is, love, trust, liking, or admiration.

Snyder et al. (1976) defined egotism as "the tendency to make attributions that put oneself in the best possible light" (p. 435). Accordingly, subjects in the present experiment displayed limited egotism. Although they strongly denied their role in undesirable events, they did not claim excessive credit for desirable events. Thus, persons may be more likely to avoid blame for blameworthy acts than they are to demand praise for praiseworthy acts. This finding is explicable in terms of the results of a study by de Charms, Carpenter, and Kuperman (1965), who found that more freedom is attributed to a person who acts in order to please a liked other than to one who acts to avoid the threat of punishment. If persons are held responsible for an act to the extent that they are perceived as having the freedom to do it or not (Harvey, 1976), then, presumably, they will be held more responsible for acts of self-aggrandizement (claiming praise) than for acts of self-protection (blame avoidance). Others may regard excessive self-aggrandizement as boastful and, therefore, undesirable. Hence, a balance between demands for a favorable public image and for a robust level of self-esteem may be struck if individuals avoid blame but do not always claim praise for their actions.

The muting of self-aggrandizement in this study seems to contradict the findings of Snyder et al. (1976), who found that egotism was as potent a factor in a bargaining game after winning as after losing. That is, their subjects were as likely to flatter themselves on success as they were to deny personal responsibility for failure. However, the competitive nature of the bargaining game may have led the subjects to adopt an assertive "heads I win, tails you lose" attitude toward the situation. Similarly, when competing only against themselves, actors are more likely to take credit for their successes than their failures (Harvey, Arkin, Gleason, & Johnston, 1974; Johnson, Feigenbaum, & Weiby, 1964). The context of the present study, which involved neither competition nor achievement, might have encouraged a more even-handed set among subjects. Unfortunately, attributional data from the bargaining study of Miller and Norman (1975) do not address this particular question.

By supporting the original proposition of Jones and Nisbett (1971) that actors attribute less causality to themselves than passive observers do, the present findings contradict the results of Miller and Norman (1975). Their bargaining subjects ascribed more behavioral responsibility to themselves and perceived more disposition in their behavior than did observers. However, in the physical absence of the bargaining opponent, the opponent's behavior probably did not "engulf the field" (Heider, 1958), a presumed prerequisite for the actor–observer effect. Because the bargaining session consisted of a number of trials involving identical choices in the same situation, the actor's own behavior would seem to be the most vivid feature of an otherwise informationally impoverished setting. Such vividness would direct attention to the self, thus fostering attributions of responsibility to the self (Duval & Wicklund, 1972). Moreover, when actor–active observer role was treated as a within-subjects factor, Miller and Norman found no significant differences on ratings of responsibility or personality, in contrast to ratings of causality in the present study.

It may be argued that the artificiality of the present questionnaire format lacks impact and precludes generalization to behavioral situations (Ruble, 1973). However, actor–observer differences have been found in previous questionnaire studies (e.g., Nisbett, Caputo, Legant, & Maracek, 1973). To the extent that this technique has limited realism, it may simply underestimate the strength of actual behavioral effects. This technique also has several advantages. As each subject attributes causality for many events in a questionnaire, a wide range of events can be sampled. By contrast, the findings of Miller and Norman (1975), Snyder et al. (1976), and Stephan et al. (1976) may not generalize beyond the bargaining context that these authors used. Such situations undoubtedly elicit rivalry and face-saving strategies that may apply only to a circumscribed subset of natural settings. Within a limited period of time, it would be difficult indeed to stage, in factorial combinations, behavioral equivalents of each of many events in both passive-observer and self-relevant modes. As well, events need not be informationally or behaviorally rich before people seek to ascribe causality for them. Often, attributions are based on hearsay or on minimal information, as in the present study. Further research would benefit from a systematic sampling of a variety of interpersonal events (as by Carson's, 1969, circumplex) to identify the situations in which active observers display varying degrees of empathic or egotistic attribution. The obvious limitations of a questionnaire study would be transcended by creating behavioral situations that permit more direct extrapolation to face-to-face encounters.

Self-Esteem and Education: Sex and Cohort Comparisons Among High School Seniors

Patrick M. O'Malley and Jerald G. Bachman
University of Michigan (Ann Arbor)

The present article reports on the self-esteem of 3,183 male and female seniors in a nationwide sample of the high school class of 1977 and draws comparisons with 1,715 males from the class of 1969. It thus provides a partial replication and extension of an earlier study, which showed that educational accomplishments undergo a reduction in centrality—become less important—for self-esteem during the late teens and early twenties. One major finding is that the self-esteem of seniors was correlated with educationally relevant measures almost equally for males in the classes of 1969 and 1977. This finding appears to rule out a secular trend interpretation of the earlier study's results, thereby providing further support for a developmental interpretation. A second finding is that self-esteem correlated with educationally relevant measures about equally for males and females in the class of 1977, suggesting that the impact of educational factors is basically similar for the two sexes. A third finding is that males and females were very similar in levels of self-esteem.

A recent analysis by Bachman and O'Malley (1977), based on a sample of about 1,600 young men from the high school class of 1969, showed that self-esteem is positively correlated with educational success. The study also showed that educational accomplishments seem to have greater importance or centrality for self-esteem during the high school years than during the 5 years beyond high school. Although the data for that study were nationally representative and covered an 8-year longitudinal span, there remained at least two important limitations on the generalizability of the findings. First, and most obviously, the study was limited to young men, thus leaving it unclear whether the findings are applicable to young women. Second, the study spanned the interval from 1966 to 1974, a period in which there were important social changes, including changes in public views about the value of education. Therefore, the data left some uncertainty about whether the changing link between educational success and self-esteem reflected a genuine developmental process in late adolescence or a secular trend that affected the society as a whole.

The present article, reporting new data from a nationwide cross section of male and female seniors from the high school class of 1977, provides a partial replication and extension of the study of the class of 1969. The new data permit us to overcome both of the limitations noted above. Unlike the previous study, the findings reported here are not longitudinal; therefore, we will not be concerned with relating self-esteem to later (post–high school) educational and occupational attainments. Instead, we will see how self-esteem among seniors relates to recent educational success (high school grades), self-ratings of academic ability, college plans, and parental education. We will examine these relationships in parallel fashion for three distinct groups: senior males in the class of 1969, senior males in the class of 1977, and senior females in the class of 1977.

Analyses for this article were supported by National Institute of Education Grant NIE-G-78-0036; the data collections were supported by Office of Education Grant OE-5-85-054 and National Institute on Drug Abuse Grant DA01411. The authors thank F. Andrews, M. Gold, R. Herzog, R. Kulka, and J. Miller for their helpful comments.

One of the basis conclusions from the previous study was that

> those things having to do with a self-concept of educational success—things such as academic skills, past classroom performance, future aspirations, and the like—undergo some reduction in salience or "centrality" for the overall self-esteem of young men as they move through the final years of high school and go on to other experiences. (Bachman & O'Malley, 1977, p. 377)

The study recognized the possibility of different interpretations.

> The first interpretation, and the one which we have emphasized, is that this shift in centrality is a fairly typical part of the developmental sequence followed by young people in this society. During the late high school years and the period which follows, the young person in the process of becoming an adult increasingly anticipates and experiences situations in which self-evaluation depends on factors quite different from success in school; and this means that academic things become less dominant in shaping self-esteem. An alternative interpretation of our findings is that they reflect a particular secular trend or cultural change during the late sixties and early seventies—a general decline in the importance or value that society places upon education and educational success. Trust in government declined dramatically during this period, and some would argue that faith in education as the pathway to success has also suffered a setback. (Bachman & O'Malley, 1977, pp. 378–379)

The present analysis, by comparing data for males in the classes of 1969 and 1977, provides a means of testing whether one of the alternative interpretations outlined above is more valid than the other. First, it must be understood that the earlier longitudinal study revealed a gradual and continuing change from 1966 (start of 10th grade) through 1974 (5 years postgraduation); across a sequence of five data collections, correlations between self-esteem and educational factors grew progressively smaller (Bachman & O'Malley, 1977; Bachman, O'Malley, & Johnston, 1978). Now suppose that this gradual change reflected a substantial secular trend or cultural change affecting the relationship between self-esteem and educational success; then, unless the trend dramatically reversed during the past several years, correlations between educational factors and self-esteem should be substantially lower for seniors in 1977 compared with seniors in 1969. But suppose, on the other hand, that the earlier findings were due solely to developmental changes occurring during late adolescence; then, unless such developmental patterns were somehow different a decade later, the correlations for seniors in 1977 should be similar to those found for seniors in 1969.

A different point of interest in the present analysis is how males and females compare in the extent to which self-esteem is determined by (correlated with) various educationally relevant dimensions. Douvan and Gold (1966), in reviewing the literature on self-esteem more than a decade ago, concluded that the self-esteem of boys and girls depended to some extent on different components. Also, Rosenberg and Simmons (1975) found evidence that indicated that adolescent boys emphasized the importance of competence and achievement more than did girls. If this is true, we may expect that to the extent that boys' needs for competence and achievement depend on educational experiences, correlations of educationally relevant variables with self-esteem should be higher for boys than for girls.

A final point of interest is whether boys have higher levels of self-esteem than girls do. There have been reports that adolescent females' self-images are less favorable than males' (Rosenberg & Simmons, 1975), although others have not found differences (Drummond, McIntire, & Ryan, 1977; Rosenberg, 1965). There are good reasons why females' self-esteem should be lower than that of males, feminists would argue. The females' less advantageous position in society could easily result in lower self-esteem. Simmons and Rosenberg (1975) in their study of adolescent girls found that "at least in 1968, girls appeared to have a more unfavorable self-picture than did boys" (p. 233). As implied in the quote, an interesting question is whether that was still true in 1977. Perhaps the upheaval in women's rights and roles in the period from 1968 to 1977 resulted in an erasure of those differences.

In fact, a comparison has already been made between the findings from the 1968 study (Simmons & Rosenberg, 1975) and findings from a later, similar study conducted from 1974 to 1975 (Bush, Simmons, Hutchinson, & Blyth, 1977–1978) "to see if the new feminist ideology and movement could have had an effect on girls' self-esteem" (p. 472).

Table 1
Self-Esteem Items and Item-Index Correlations

Item	1977 high school seniors: Males n	M	SD	r[a]	Females n	M	SD	r[a]	t test between means
I take a positive attitude toward myself.[b]	1,568	4.13	.93	.54	1,736	3.98	.99	.56	**
I feel I am a person of worth, on an equal plane with others.[b]	1,555	4.27	.85	.49	1,727	4.21	.90	.55	
I am able to do things as well as most other people.[b]	1,560	4.41	.75	.39	1,733	4.30	.81	.50	**
On the whole, I am satisfied with myself.[b]	1,539	4.06	1.05	.48	1,718	4.06	1.03	.57	
I feel I do not have much to be proud of.[c]	1,519	4.03	1.14	.54	1,707	4.05	1.15	.60	
Sometimes I think that I am no good at all.[c]	1,506	3.63	1.32	.51	1,701	3.47	1.39	.50	**
I feel that I can't do anything right.[c]	1,498	4.07	1.11	.41	1,695	4.11	1.08	.53	
I feel that my life is not very useful.[c]	1,501	4.18	1.05	.60	1,687	4.18	1.10	.62	*
Self-esteem index	1,494	4.10	.66	.79[d]	1,689	4.04	.72	.83[d]	

[a] Item-index correlation, corrected for part–whole.
[b] Response of "agree" coded 5 (high self-esteem).
[c] Response of "disagree" coded 5 (high self-esteem).
[d] Coefficient alpha.
* $p < .05$. ** $p < .01$.

Like the 1968 study, this more recent study found that girls' self-esteem in the sixth and seventh grades averaged slightly lower than boys'. The present study extends the time period to 1977 and looks at seniors, rather than sixth and seventh graders.

In sum, this article employs data from two studies to address three theoretically important questions about self-esteem. First, are the patterns of correlation between self-esteem and educational factors essentially the same for males in the high school classes of 1969 and 1977? Second, are these patterns of correlation similar for males and females (in 1977)? Third, are there differences in levels of self-esteem between males and females (in 1977)?

Method

Sample

One source of data is the Youth in Transition sample of young men from the high school class of 1969, described in detail by Bachman et al. (1978). Briefly, this is a nationally representative sample of 2,277 sophomores in 87 schools in the 48 contiguous states. Data collections were made in 1966 when they were sophomores and again in 1968, 1969 (when they were seniors), 1970, and 1974. In the 1969 data collection, the one most relevant here, 1,799 participated (79% of the original target sample).

The second source of data is the Monitoring the Future project being conducted by the University of Michigan's Institute for Social Research. The study is described in detail by Bachman and Johnston (Note 1); only a brief overview is given here. The project consists of a series of annual questionnaire surveys of male and female seniors in high school. In addition, annual follow-up surveys are mailed to a subset of each sample for 6 years following their graduation. The initial base-year data collection is conducted in about 125 schools selected to provide an accurate cross section of high school seniors throughout the United States. The 1977 base-year survey of over 18,000 seniors provided the data to be reported here.[1] The measure of primary interest, self-esteem, was included in only one of the five forms used in the study, so analyses in this report were based on an essentially random 20% of the total. The number of respondents with complete data on the self-esteem index was 3,183.

[1] The study began with the class of 1975; however, 1977 was the first year that included all of the eight self-esteem items presented in this article.

Measures

Self-esteem measures in the two studies were similar but not identical. The Monitoring the Future measure was an eight-item index similar to that used by Rosenberg (1965). Respondents were asked to indicate on a 5-point scale the extent of their agreement or disagreement with the items. The response categories—disagree, mostly disagree, neither, mostly agree, agree—were coded from 1 to 5, with higher values assigned to responses indicating higher self-esteem. The first four items were positively worded, and the second four were negatively worded. Table 1 shows the eight items, with their means, standard deviations, and item-index correlations, separately for males and females. Coefficient alphas were .79 for males and .83 for females.

The measure of self-esteem used in the Youth in Transition study differed slightly from the Monitoring the Future measure. A different 5-point scale was used; respondents were asked to indicate how often each item was true for them, with responses ranging from almost always true to never true. There were 10 items, 7 of which were virtually identical to those used in the 1977 Monitoring the Future study (Items 1–3 and 5–8 in Table 1). (See Bachman & O'Malley, 1977, for the Youth in Transition item wordings, means, standard deviations, and item-index correlations.) Coefficient alpha for males in the class of 1969 was .79, the same as the value for males in the class of 1977.

Because the two studies employed different response scales, and some different items, it is difficult to compare means and standard deviations directly. However, because the two measures are very similar in their basic content as well as index characteristics (coefficient alphas and item-index correlations), their correlations with other measures should be comparable. (The comparability can be heightened by using subscales based on the seven common items. The present article includes correlations based on these subscales. To maintain comparability with other reports using these data, however, we focused primarily on the complete 10-item and 8-item measures.)

Unless otherwise stated, the remaining measures listed below are the same in the two studies.

Father's education and mother's education were measured on a 6-point scale ranging from grade school or less to graduate or professional school. Parental education is a mean of father's and mother's education. Grades were self-reported on a 9-point scale. In the Youth in Transition sample, the grades for junior and senior years were averaged together; in the Monitoring the Future sample, respondents were asked for "your average grades so far in high school."

College plans is a dichotomy indicating whether the respondent planned to enter college or not. Self-concept of school ability is a mean of two items that asked respondents to compare themselves, on a 7-point scale, with others of the same age on school ability and intelligence. For the class of 1969, the measure was obtained as of junior year; for the class of 1977, the measure was made as of senior year.

Statistical Significance

In reporting statistical significance levels, we made no adjustment for the clustered sampling design used for both samples. One reason for not adjusting for design effect was that we did not have good estimates of the design effect for self-esteem and its correlations with other variables. We are confident, however, that these design effects are small because there is little clustering of self-esteem by school. Since the nominal probability levels are nevertheless likely to be slightly inflated, we report statistical significance at both the .01 and the .05 levels.

Results and Discussion

Class of 1977: Male Versus Female Levels of Self-Esteem

Table 1 shows that responses to the self-esteem items for males and females in the class of 1977 indicated a generally high level of self-acceptance. The average response was just above "mostly agree" for the positive items and about "mostly disagree" for the negative items. On six of the eight items, males were higher in self-esteem than females (three of these significantly so); for the total index, males were significantly higher ($p < .05$). Females were more internally consistent, however, as indicated by the higher item-index correlations for all but one item, and the higher coefficient alpha.

The fact that self-esteem was slightly lower for females than for males is consistent with Simmons and Rosenberg (1975) and Bush et al. (1977–1978). Apparently, the recent activities aimed at upgrading women's position in society have not resulted in a total elimination of the differences in self-esteem for high school seniors. But perhaps more important is the fact that the difference in Table 1 is small indeed—less than .09 of a standard deviation. This very small difference is statistically significant given a large number of cases, but studies that use smaller samples would be unlikely to show statistically significant differences. This may explain why Maccoby and Jacklin (1974) reported that statistically significant sex differences were seldom found. They commented that "the similarity of the sexes in self-esteem is remarkably uniform across age levels through college age" (p. 153). But their review was based on a number of studies, most of which involved small samples.

Table 2
Correlations of Self-Esteem With Educational Measures for Seniors in 1969 and in 1977

Measure	Youth in Transition (Class of 1969)	Monitoring the Future (Class of 1977)	
	Males (n = 1,715)[a]	Males (n = 1,494)[a]	Females (n = 1,689)[a]
Father's education	.09 (.10)	.08 (.09)	.11 (.11)
Mother's education	.06 (.07)	.07 (.07)	.08 (.08)
Parental education	.08 (.10)	.08 (.09)	.11 (.11)
Grades	.21 (.21)	.25 (.26)	.24 (.26)
College plans	.18 (.19)	.18 (.20)	.14 (.16)
Self-concept of school ability	.27 (.26)	.28 (.29)	.29 (.30)

Note. All correlations are significantly different from zero at the .01 level, except that between self-esteem and mother's education, for the 1977 senior males, which is significant at the .05 level. The correlations in parentheses are based on the subscale that consists of the 7 items common to both studies (Items 1–3 and 5–8 in Table 1). In no case does a subscale correlation differ from the corresponding full scale correlation by more than .02. The 7-item subscale correlates .95 with the 10-item Youth in Transition measure, .98 with the 8-item Monitoring the Future measure for males, and .99 for females. Subscale coefficient alphas are .76, .76, and .80 for the three samples, respectively.
[a] The number of cases varies slightly for each correlation, with up to 8% missing data.

There is another large-scale study of a nationally representative sample of high school seniors that included a measure of self-esteem similar to those used in the present articles, namely, the "National Longitudinal Study of the High School Class of 1972." Using these data, Conger, Peng, and Dunteman (Note 2) reported that female seniors were statistically significantly lower in self-esteem than males by about .10 of a standard deviation.

A further note of consistency in the finding of slightly lower scores on self-esteem for females than for males comes from the Monitoring the Future data collections from seniors in 1975 and 1976. In those years, an abbreviated four-item self-esteem scale was used. In each year, the females averaged slightly lower than the males.

One other point should be made. Our discussion thus far has taken these self-reports of self-esteem at face value and dealt only with bivariate relationships. It is possible that a more substantial difference between sexes in self-esteem—or even a reversal of the difference reported here—is being masked or suppressed by other related variables that we have not controlled (Rosenberg, 1973). There are several likely candidates for such suppressor variables. Maccoby and Jacklin (1974) noted that boys score higher on lie or defensiveness scales. Thus, boys might defensively overrate themselves on the self-esteem measures. If so, girls may actually have higher self-esteem than boys. A related possible suppressor is social desirability, the tendency to present oneself in as favorable a light as possible. Bush et al. (1977–1978) included such a measure in their study and found that girls were higher than boys in social desirability. Thus, their findings that females were slightly lower in self-esteem could not be due to a social desirability effect. If anything, the differences would be greater if social desirability were controlled. But the correlations among all the variables in their study were low, and controlling actually made little difference in relationships; the zero-order and partial correlations were similar.

Finally, in the Monitoring the Future data, grades could be suppressing a sex effect on self-esteem. We demonstrate that grades and self-esteem are positively correlated; further, females report higher grades than males (data not shown here). Therefore, one would expect females to show higher self-esteem. The fact that they showed lower self-esteem indicates that self-esteem differences would be greater if grades were controlled. But again the differences between zero-order and partial relationships were small. The zero-order correlation of .04 between sex and self-esteem becomes a standardized regression coefficient

of only .08 when grades are controlled, and the substantive significance of a regression coefficient of .08 is dubious indeed.

In sum, the data on sex differences in self-esteem among adolescents showed some consistency across studies and across time. Females scored slightly lower than males, but so slight were the differences that relatively large samples were required to achieve statistical significance. Such differences—on the order of .10 of a standard deviation or less—are of dubious substantive significance. As Maccoby and Jacklin (1974) pointed out, it is the similarity, not the difference, that is remarkable. Although there remains the logical possibility of substantively important effects of sex on self-esteem, the various suggested controls—some of which serve to heighten self-esteem differences between the sexes and some of which serve to lessen differences—do not appear to be sufficiently strong to alter the conclusion that self-esteem scores are distributed similarly among males and females.

Classes of 1969 and 1977: Educational Variables and Self-Esteem

Now we turn to correlations between self-esteem and measures of parental education, grades, college plans, and self-concept of school ability. We compare these correlations, obtained separately for males and females, with those in the Youth in Transition sample of boys in the high school class of 1969.[2] Table 2 shows these correlations. The basic import of Table 2 is that the correlations of self-esteem with the various measures of background, achievement, and aspirations are all similar among the three groups. None of the pairwise comparisons between groups showed a statistically significant difference. In other words, (a) the correlations for male seniors were stable across the 8 years from 1969 to 1977 and (b) the correlations were similar for both males and females in the class of 1977.

This second finding is rather important. As noted earlier, Douvan and Gold (1966) concluded that the self-esteem of boys and girls depended to some extent on different components. The data in Table 2 suggest that the self-esteem of male and female seniors does not depend differentially on the components listed there.

The first correlational finding—that the self-esteem of male seniors correlates with educationally relevant measures about equally for the classes of 1969 and 1977—provides an extension and replication of part of the findings of the previous report. Although it does not deal with the longitudinal aspects of that report, by replicating the cross-sectional aspects it provides some added support for the conclusions reached there.

It appears that self-esteem in high school does depend to some extent on factors of background, achievement, and aspiration. All correlations in Table 2 are positive, and some are at least moderately high (i.e., grades and self-concept of school ability). (All of the correlations in Table 2 are significantly different from zero.)

As discussed above, the earlier longitudinal analysis found that "educational success and its correlates seemed to grow less central to the self-esteem of young men . . . as they moved through high school and beyond," and this was interpreted as "a fairly typical part of the developmental sequence followed by young people in this society" (Bachman & O'Malley, 1977, p. 378). But an alternative explanation was that there was an overall secular trend involving a lessening importance of education for self-esteem—a pattern that would be reflected in reduced correlations between education and self-esteem in later cohorts of students. If the data presented in Table 2 had shown lower correlations for the 1977 seniors (male) than for those from the class of 1969, the secular trend interpretation would have been supported. In fact, however, Table 2 shows a striking degree of similarity in the relationships for the two cohorts; certainly the correlations for the class of 1977 are not at all lower than those for the class of 1969.

Thus, by failing to confirm the secular trend interpretation, the present replication and extension provides additional, albeit indirect,

---

[2] Because the Monitoring the Future sample design eliminated high school dropouts, the present computations for the Youth in Transition sample also eliminate dropouts. The number of cases is therefore slightly different from the earlier report that included dropouts (Bachman & O'Malley, 1977).

support for a basic conclusion from the earlier study: Educational success becomes less central to self-esteem during late high school and the years that follow. Furthermore, given the high degree of similarity between male and female self-esteem data in the class of 1977, it is likely that this process holds true for both sexes.

Deindividuation, Self-Awareness, and Disinhibition

Ed Diener
University of Illinois at Urbana-Champaign

This study was designed to discover whether lack of self-awareness, group unity, lack of conscious planning, and disinhibited behavior occur together in deindividuating settings, as predicted by Diener's theory of deindividuation. Another purpose of the study was to compare the characteristics of deindividuation in groups with the characteristics of lack of self-awareness induced in a nonsocial way. Three conditions were compared: deindividuated, non-self-aware, and self-aware. After the manipulations, participants could choose inhibited versus disinhibited tasks in a supposed "creativity" session, followed by a variety of deindividuation measures. When the dependent variables were factor analyzed, key components of deindividuation loaded together on a single common factor. The results also revealed that the deindividuation group surpassed the other two on the deindividuation factor ($p < .001$) and on most of the individual measures. For some of the variables, the deindividuation and non-self-aware groups differed significantly, suggesting that deindividuation may not be identical in every respect to lack of self-awareness induced in a nonsocial way.

Festinger, Pepitone, and Newcomb (1952) suggested that persons may not be perceived as individuals in some groups. They argued that these "deindividuated" people are freed from restraints and are likely to perform behaviors they would usually inhibit. Zimbardo (1970) further theorized that there are certain input variables that cause deindividuation, certain inferred internal changes such as minimal self-evaluation, and certain "output behaviors" that characterize the state. Spurred by Zimbardo's theory, a number of studies have been conducted that have explored deindividuation in the laboratory (e.g., Baron, 1971; Diener, Westford, Dineen, & Fraser, 1973; Dion, 1971; Maslach, 1974), in field settings (e.g., Diener, Fraser, Beaman, & Kelem, 1976), and cross-culturally (Watson, 1973). Past research, which has been reviewed in detail elsewhere (Diener, 1977; Dipboye, 1977), has focused almost exclusively on the relationship between specific input variables and the resultant behavior. Thus, the majority of the findings can be interpreted in terms of discriminative stimuli for disinhibited behavior without recourse to the concept of deindividuation.

Diener attempted to provide direct support for deindividuation by measuring the internal changes that Zimbardo's (1970) theory suggested should accompany the situational inputs (Diener, 1976; Diener, Dineen, Endresen, Beaman, & Fraser, 1975). He manipulated factors such as anonymity and responsibility and measured aggressive behavior and internal cognitive changes as well. He assessed, for example, memory and self-consciousness. The findings did not appear to offer strong support for the theory. The cognitive measures in most cases did not correlate with the overt disinhibited behavior, and no strong central factor was found when the measures were factor analyzed. However, when the paradigm employed in these studies is considered, it is not surprising that deindividuation did not occur. After subjects were exposed to the manipula-

My thanks are extended to Robert Flax, Thomas Srull, and Carol Diener for their help in conducting the study and preparing the manuscript. I also appreciate the insightful comments of Charles Carver, and the anonymous reviewers.

tions, they were observed while they "tested a pacifist" by being physically aggressive to him. In such a laboratory situation, subjects were undoubtedly quite self-conscious. In conclusion, past findings on the behavioral consequences of deindividuating conditions have offered some support for the theory. However, no study has found that subjective experiences such as lack of self-awareness or feelings of group unity follow deindividuating conditions and covary together.

Cognitive Factors Underlying Deindividuation

The theory of self-awareness (Wicklund, 1975, 1979) has much in common with the theory of deindividuation. Duval and Wicklund (1972) hypothesized that self-aware persons are more likely than non-self-aware persons to behave in accord with personal and social standards. Much empirical evidence has been accumulated that supports this formulation (e.g., Carver, 1974, 1975; Diener & Srull, 1979, Diener & Wallbom, 1976; Rule, Nesdale, & Dyck, 1975; Scheier, Fenigstein, & Buss, 1974). Given the pivotal position of attention to oneself as a separate entity in both the theories of self-awareness and deindividuation, several authors have suggested that a conceptual integration is in order (Diener, 1977; Duval & Wicklund, 1972), and Ickes, Layden, and Barnes (1978) have found empirical support for such an integration.

Recently Diener (1979) advanced a theory of deindividuation that borrows from the theory of self-awareness, from behavioral theories of self-regulation (Bandura, 1976; Kanfer, 1977), and from earlier models of deindividuation. In Diener's theory, monitoring of one's own behavior and awareness of oneself as an individual are necessary for self-regulation (cf. Carver, in press) and are prevented by certain factors present in some groups. Diener has lessened the emphasis on anonymity as a cause of deindividuation and stressed instead group cohesiveness and uniformity (Ziller, 1964), group activity, and an outward focus of attention. Each of these seems to be a likely cause of deindividuation because it can diminish or prevent self-awareness. According to this theory, the deindividuated person is blocked by environmental factors from becoming self-aware and is thus less likely to regulate his or her behavior in reference to personal and social standards and long-term planning considerations, and more likely to react to immediate cues, motivations, and emotions. Although antisocial behavior does not necessarily result from deindividuation, the person is more influenced by situational factors and less concerned with standards.

Purposes of the Study

The present study was designed to assess whether deindividuation is a useful construct and actually represents a unitary experiential and behavioral phenomenon. A major purpose of the study was to implement seemingly deindividuating conditions and measure both the behavior and the other changes that are defining characteristics of the concept. When in deindividuating circumstances, according to Diener's theory, persons should be less self-aware, plan ahead less, feel close to the group, and be more disinhibited than usual. Therefore, persons in deindividuating situations should have higher scores on the average on each of the central measures of deindividuation than persons who are not in such settings. In addition, these characteristics (low self-awareness, group unity, and disinhibition) should occur together within deindividuated persons and form a single factor when factor analyzed. In the present study, conditions thought to produce deindividuation were maximized, and multiple measures of disinhibited behaviors and postulated intervening cognitive variables were employed. A number of improvements over previous studies (Diener, 1976; Diener et al., 1975) were introduced that seemed likely to increase the likelihood of occurrence of deindividuation.

A second purpose of the present study was to compare the characteristics and effects of group-induced deindividuation with nonsocially induced non-self-awareness. Although Diener's (1979) theory maintains that deindividuating conditions block self-awareness, it seems likely that nonsocial conditions, for example, viewing an exciting movie, can also minimize self-awareness. However, group deindividuating conditions may be more certain to prevent

self-awareness because they not only direct attention away from the self, but also focus attention explicitly on the group. Thus, attention may be less likely to drift back to the self.

A last question addressed by the present study is, What are the characteristics of deindividuation beyond those mentioned earlier? Although group unity and lack of self-awareness are defining characteristics of deindividuation, many additional components have been suggested. For example, Festinger et al. (1952) suggested memory impairment regarding the acts of individual persons. Zimbardo (1970) suggested several additional characteristics such as amnesia, perceptual distortion, and emotionality.

In summary, the major purpose of the present study was to create a situation that appeared to be deindividuating and to assess whether the characteristics, both overt and covert, predicted by the theory result from this situation. A factor analysis of the measures was planned to reveal whether the hypothesized components of deindividuation occur together within individuals. Another purpose of the study was to compare the characteristics of deindividuation and lack of self-awareness resulting from nonsocial causes. Finally, the study was to ascertain the characteristics of deindividuation beyond those that define the state, for example, whether altered state experiences accompany deindividuation.

Method

Overview

The experiment was a 2 × 3 (Sex × Condition) design with the three conditions being deindividuation, non-self-aware, and self-aware. Participants were 59 male and 67 female subjects with 42 persons in each of the three conditions. After a half hour of group activities that were designed to create the three levels of group feeling and self-awareness, subjects were allowed to participate in activities that might "enhance their creativity for a later creativity test." This subsequent session, which was labeled the "individual" session for subjects, was actually the session in which evidence of the behavioral disinhibition was gathered. In the "individual" session participants could choose from disinhibited or inhibited tasks. Subjects were also asked to make creative verbal statements (which could be inhibited or disinhibited) at certain times during the so-called individual session. These two activities following the manipulation session served as the measures of disinhibition. After these activities, participants completed memory measures and an inventory assessing self-reported self-consciousness, group unity, and so on.

Setting

A group of eight same-sex introductory psychology students participated in each session, but unknown to the two real subjects, six of the persons were confederates who manipulated group factors in a preprogrammed way. Although the experimenter was always a male, he was assisted in running the experiment by two persons who were the same sex as the confederates and the subjects at that session. The eight participants (six confederates and two subjects) were either all males or all females at any one session. The experiment was run in a large room during evening hours and was said to be concerned with creativity. Subjects were told that the first session was a series of group activities designed to limber their minds up and get them in touch with their feelings. This group session provided the context for the manipulations. Subjects were told they would next work in an "individual session" in which they would all still be together, but in which each participant could choose the tasks he or she wanted to work at. Other sessions that would test creativity were alluded to later in the period. In other words, the first two sessions were presented as though they were designed to enhance creativity. Following these sessions, however, the two subjects actually completed the memory measure and questionnaire.

Conditions

A series of activities was developed for the three conditions. The manipulations for each condition during the group session lasted about 30 minutes. Male subjects only were run on Monday and Wednesday evenings and females on Tuesday and Thursday evenings, with the conditions being systematically rotated over evenings. The study occurred over an 8-week period. Subjects were phoned a day ahead of their appointment and asked to wear old clothes to the study.

Self-awareness condition. Subjects in the self-aware conditions were exposed to a group atmosphere and to activities designed to heighten feelings of individuality and self-awareness. In the waiting room the confederates acted fidgety and self-conscious. After the initial instructions the group was divided into a larger group (the confederates) and a smaller group (the two subjects) and taken to separate rooms to work at different tasks. It was stated that later all subjects would rotate in pairs through the one task, and in the meantime the others would complete some questionnaires. Once in the experimental room, the two subjects were asked to put on mechanics' long-sleeved coveralls to "protect their clothes" during the possibly messy later activities.

The two subjects were given name tags, seated at a large table, and then exposed to a series of manipulations designed to heighten their self-awareness. These were presented as ways of helping them get in touch with feelings and their inner self. Subjects, addressed

by name by the experimenter, first listened to music and answered questions about how it matched their personality characteristics. Next they wrote an essay about themselves, covering such topics as what makes them unique. They also listed their hometown, hobbies, personal motto, and other individuating information. They next read all the personal information to the other subject (being allowed to omit anything they felt was too personal). The subjects then answered questions about themselves compared to the other subject, for example, "Who do you think is probably more creative?"

At this point the research assistant brought in the six confederates who had ostensibly been working at a different task in another room. The assistant said that they had been told about the coveralls but that they preferred not to wear them. Since the phone caller who reminded them of their appointment had asked them to wear old clothes, they were not concerned if their clothes got dirty. Several confederates agreed that they preferred not to wear the coveralls and the experimenter, seemingly surprised, allowed them to proceed without coveralls if they weren't "worried if their clothes get dirty." Therefore, the two subjects stood out from the rest of the group because of their attire. The experiment next entered the "individual" phase of the study. At this point, the participants in the self-aware condition were dressed differently from the six confederates, had been exposed to a series of individuating tasks, and were part of a noncohesive group.

Non-self-aware condition. The confederates in this condition were pleasantly friendly but not outgoing. Subjects were exposed to a series of manipulation activities designed to focus their attention outward. The confederates and subjects performed the activities as a group throughout this condition and were all dressed in the coveralls. For example, they listened to music and rated its qualities and also rated jokes. They wrote how universities would be different in 100 years. Subjects also wrote a rebuttal to a letter that criticized university students. Next they worked on a series of challenging and fun games and puzzles. The emphasis in each activity was to relax and become more creative, and it was stated that none of the activities would be evaluated.

During the "individual" session these subjects were asked to press a pedal rhythmically throughout the session. Although this was said to be a trial activity to help judge the effects of rhythm on creativity, it was actually designed to be slightly distracting and thus reduce self-awareness (Duval & Wicklund, 1972) as the session continued. No names or name tags were used in this condition. Thus, this condition was designed to involve subjects in activities that would not accentuate individuality but would direct their attention outward away from themselves. No competition was created within the group, but neither was a spirit of group unity generated.

Deindividuation condition. In the waiting room the confederates were friendly and attempted to create a close group feeling in this condition. They spoke to the entire group, not to single individuals. The experimenter asked them to adopt a group name, and he thereafter called the group by this name. He said this name would be used to label their data, which were to be "treated as a group, not on an individual basis." The group was given the coveralls, and the confederates made putting them on a unifying and fun event. The first activities were designed specifically to draw the group together. Group members sang together and then did "elevation"—getting "psyched up" and together lifting an assistant high in the air. The group next formed a circle by interlocking arms and were told to prevent one of the assistants from breaking into the circle. The next activity, African dancing, was designed to continue the group-cohesive activities, but was also intended to produce the arousal, group coordination, and kinesethetic sensory experience that seems to be a part of many groups in which disinhibition occurs (Sargant, 1975). During the loud Burundi drum music, the group clapped in unison, swayed in unison, and danced around in a circle together. The lights in the room were dimmed. Thus, subjects in this condition were exposed to a variety of manipulations designed to create a unified group. To carry on the group feeling during the individual disinhibition session (in which subjects were seated around a large table) the confederates made occasional remarks to the group.

Measures

There were four major sets of measures: (a) activity disinhibition during the individual task, (b) speech disinhibition during the individual task, (c) memory measures taken after the "individual" session, and (d) a postexperimental questionnaire measuring group feeling, self-consciousness, altered state experiences, and so on.

Disinhibition tasks. Immediately after the manipulation session in which varying levels of group feeling and self-consciousness were induced, subjects moved to the "individual" session. They made their choices of the tasks they wanted to do, and each took a seat around a large square table. In front of each participant was a cue light, a microphone, and a list of the activity boxes available for this part of the experiment.

It was desirable to use tasks that were different in their social appropriateness but roughly equivalent in interest and fun. Two sets of tasks were created, disinhibited tasks in colorful boxes and inhibited tasks in dark brown boxes. In a pilot study 12 male and 13 female undergraduates had rated a large list of potential tasks on a scale for inhibition–disinhibition and a scale for boring/aversive versus interesting/fun. Twenty disinhibited tasks were selected and matched with 20 inhibited tasks that averaged the same score on interesting/fun. Since there were sex differences in the ratings, the 40 tasks were selected so that these differences were minimized on both the interest and disinhibition dimensions. On the 9-point disinhibition scale, the 20 inhibited tasks had a mean of 3.15, and the 20 disinhibited tasks averaged 6.45. However, the interesting/fun value of the tasks was similar (5.40 vs. 5.25). Examples of tasks and their ratings are shown in Table 1.

The tasks were grouped together in sets of four, and these tasks all came together in a box. For example, an inhibited box labeled *Intellectual challenges* contained

Table 1
Examples of Tasks and Ratings

Task	Interesting/fun rating[a]	Disinhibition rating[b]
Inhibited task		
Crossword puzzles	4.34	2.39
Reading about disarmament	6.64	2.00
Answering moral dilemma questions	5.57	4.01
Playing "Hi-Q"	3.83	3.71
Answering comprehension questions about a story	6.41	3.17
Disinhibited task		
Playing in mud	4.84	7.18
"Finger painting" with your nose	4.93	7.71
Writing the faults of your friends	6.24	5.03
Sucking liquids from baby bottles	6.34	6.84
Writing down all the obscenities you can think of	5.80	5.52

[a] Low = fun. [b] Low = inhibited.

four tasks such as "Hi-Q," pencil mazes, and so on. There were five types of boxes for the inhibited tasks and five types of boxes for the disinhibited ones. Each type of box had a label that broadly described the tasks inside (e.g., *Unusual foods*, *Desecration*, and *Public issues*). These box labels were also selected based on preratings so that they differed on rated disinhibition (7.9 vs. 4.16) but not on interesting/fun (4.2 vs. 4.38).

Subjects were told that during the individual session (lasting 20 minutes) they could choose any box they liked. They could see the boxes and their labels but did not know the contents (tasks) unless they selected that box. They could work in a box for as long or as short a time as they liked and do any number of tasks within it. When they tired of that box, they were to select another. Initial selections were made on a sheet of paper that contained a list of all the inhibited boxes in one column and all the disinhibited tasks in the other. Subjects were asked to make three ranked choices initially in case "we run out of a particular box." These three initial choices were weighted by their order to produce a measure of disinhibition of the initial choices. The experimenter and an assistant brought the new boxes when they were desired.

Subjects were told before the individual session that they should feel free to choose either type of box, since both "can probably enhance creativity." They were told that in the dark boxes were intellective tasks that could stimulate their minds and get them thinking quickly. They were reminded that quick thinking is an essential part of creativity. The experimenter said that the tasks in the colorful boxes could also enhance creativity by helping them get in touch with feelings and sensations. It was repeated that they should feel free to switch boxes whenever they liked and that they could choose any box or combination of boxes they wanted.

Two confederates seated at the far end of the table from the subjects recorded which boxes and tasks the subjects chose. Since these confederates were apparently working in boxes requiring writing, their writing did not seem strange and never attracted attention. The recording confederates also wrote down a description of the subject's behavior. These descriptions were later rated for the degree of disinhibition exhibited by the subject by raters who were blind as to the subject's condition. Each confederate chose the same boxes regardless of condition and did the same tasks in every condition. Four of the six confederates initially chose disinhibited boxes, and then they switched tasks in a preprogrammed regular way, the overall new choices being approximately half disinhibited boxes.

Speech measure. Subjects were asked to make several "creative statements" into a microphone during the individual session. These statements were to be made whenever a cue light came on in front of the person. The order of lights was always the same and allowed each subject to make three statements and each confederate to make two. The confederates made the same standard statements in all conditions, with some of their statements being rather unusual, creative, or disinhibited, and some being mundane and ordinary. An example of a statement is, "This reminds me of when I was young, exploring new things and acting crazy. I feel like a child again without a care in the world."

Subjects were told in the self-aware condition that their statements would be individually recorded. In the non-self-aware condition it was mentioned simply that the statements would be recorded. In the deindividuation condition it was stated that all the group would be recorded together and labeled with the group name. The recorded statements of the subjects were rated by two raters who scored the subject's three statements on inhibition–disinhibition. The ratings for the subjects were averaged across their three speeches. The two raters' scores were correlated across subjects, and since the interrater agreement was high ($r = .82$), the average score for the two raters was assigned to that subject.

Postexperimental questionnaire. After the individual session, subjects were taken to a different room and the research assistants administered the postexperimental

Disinhibition of speech[c]	.37	.04

[a] Deindividuation. [b] Altered experiencing. [c] Did not load above .4 on either factor.

questionnaire and memory measures to them. The questionnaire contained a series of items, most rated on 9-point bipolar scales: (a) subjective feeling of time passage; (b) self-reported self-consciousness; (c) memory for the tasks the person next to them did (essay format); (d) perceived similarity to other participants and feeling of group unity and liking; (e) enjoyment of the session; (f) reports of altered perceptions, thinking, and emotions; (g) reports of an altered state of consciousness (yes or no answer) and other unusual experiences such as hallucinating; (h) the extent to which their behavior was guided by conscious planning versus flowing with the environment and making spontaneous choices; (i) memory measures for peripheral cues in the room such as the content of posters on the walls; and (j) suspicion measures, including suspicion of the confederates and guessing the purpose of the experiment.

Memory measures. Each subject was asked to select the photographs of persons who had been in their group and of persons not in their group. There were pictures of all six confederates and six filler photos of other undergraduates. Subjects were required to sort all of the pictures into two piles. Thus, a subject could score from 0 to 12 pictures correct. The same procedure was carried out for statements that had been made during the session. Ten correct confederate statements (out of the 12 made) written on cards were presented together with 10 filler statements that had not been said, and subjects were asked to sort them all into two piles. Next, the 6 veridical pictures and the 10 actual statements were given, and subjects were asked to match all the statements with the picture of the person who said them, even if they had to guess on some. Subjects could not keep track of how many statements each of the confederates made while they were involved in the task. Also, they did not necessarily receive two statements from each confederate. Thus, participants could match from zero up to several statements to a particular confederate. Therefore, the task was really one of matching each statement to the confederate who was most likely to have made it. Lastly, subjects were given six statements and asked to select the three they had made.

Ethical Precautions

Since the study involved deception and some unusual activities, a series of ethical precautions were used, and these are briefly described here. The initial instructions emphasized subjects' right to withdraw at any time and their right to refuse to do anything they did not wish to do in the experiment. Subjects were cautioned not to engage in any physical activities contraindicated by health problems. The confederates intervened if any subject's behavior became too extreme during the individual session (e.g., eating mud). The debriefing was conducted carefully and took 15–20 minutes. Each subject was introduced to facts about the study in a graduated way as recommended by Mills (1976), was promised anonymity, and his or her feelings about the study were discussed. In general, the ethical guidelines recommended by Diener and Crandall (1978) were followed. Many subjects afterward said it was the most interesting study in which they had participated.

Results

Factor Analysis

Sixteen of the major variables were subjected to a principal axis factor analysis with multiple correlations employed as the communality estimates. A solution with two factors was chosen based upon the scree of the eigenvalues (Cattell, 1966), the interpretability of the data, and the factor loadings. The solution was subjected to an orthogonal (varimax) rotation. For both factors the items with absolute weights above .4 are shown in Table 2.[1] The factor loadings reflect simple structure except for the case of group liking and group unity, which loaded substantially on both factors. The five variables that did not load above .4 on either factor are also shown in Table 2. The major factor contains the key elements of deindividuation, including group unity and liking, low self-awareness, spontaneity, and disinhibited behavior. The second factor also contained group unity and liking, but was otherwise composed of altered experience items. Thus, across subjects the key variables formed two major independent factors, one that can be labeled Deindividuation and the other that can be labeled Altered Experiencing. It appears that the memory items were mainly those that did not load on either factor. The first-order correlation between conscious planning and group unity was $r(124) = -.45$, $p < .001$. The correlation between the disinhibition score of tasks chosen and self-awareness was $r(124) = .38$, $p < .001$.

Effect of Conditions

The two factor scores for each subject were standardized, and a multivariate analysis of variance (MANOVA) was performed on the two scores. These data were collapsed across sex because this factor produced negligible differences on most variables. Thus, the MANOVA was computed on the three conditions with the two dependent variables. Pillai's Trace Criterion V transformed to a standard F revealed that the three conditions were significantly different, $F(4, 246) = 8.79$, $p < .001$. This method is one of several for calculating a MANOVA significance test, and is suitable for the present data (Olson, 1976). A multivariate extension of omega-square revealed that condition accounted for 23% of the variability in the dependent measures. The mean standardized factor scores and the univariate tests on the factors are shown in Table 3. Newman-Keuls comparison of means (significant differences designated by the subscripts in Table 3) reveals that the deindividuation group scored significantly higher on Factor 1 than the other two groups, who did not differ significantly from each other. On Factor 2 the deindividuation group was significantly higher than the self-aware group only.

The factors were also subjected to a discriminant analysis, and the discriminant functions were used to predict the probability that each subject was a member of each condition (Cooley & Lohnes, 1962). This procedure properly classified 74% of the deindividuation subjects (gave the largest probability that they were in the deindividuated group), 21% of the non-self-aware subjects, and 60% of the self-aware subjects. This procedure predicted that 33% of the non-self-aware subjects belonged to the deindividuated group and that 45% belonged to the self-aware group. It appears that some subjects in the non-self-aware group reacted in a manner similar to the deindividuation subjects and some in a way similar to the self-aware subjects.

Univariate data and analyses of variance on the individual variables are also shown in Table 3. Although sex of subject did produce significant main effect differences on a few of the individual variables, it did not result in significant interactions with condition, and these results tended not to be theoretically interesting. For this reason the sex data and analyses are omitted from Table 3. Although

---

[1] A stable factor-analytic solution depends on having a large number of subjects relative to the number of items to be factored. Therefore, a number of items were not included in the factor analysis, bringing the number of factored items to 16. The 10 items that were excluded either were redundant with other items or were of lesser importance to the theory of deindividuation. The excluded items were rated disinhibition of behavior; concern over what experimenter would think of you; similarity to the group; enjoyment of the group session; emotions, thinking, and perceptions altered from normal (3 items); memory for the confederate photographs, for peripheral cues, and for tasks neighbor did (3 items).

Table 3
Mean Scores for Factors and Individual Variables

Variable	Condition: Deindividuated	Condition: Non-self-aware	Condition: Self-aware	Univariate *F*

Note. Multiple comparisons conducted only where main effect was significant. Means across the same row with the same subscripts in the same letter series are not significantly different (Newman-Keuls or χ^2) at $p < .01$ (abc) or $p < .05$(xyz).
[a] Items scored so that a low score indicated a greater magnitude of the item as labeled.
* $p < .05$. ** $p < .01$. *** $p < .001$. **** $p < .0001$.

the MANOVA was highly significant, the univariate alpha levels should be treated cautiously, since there are a large number of non-independent tests presented. In addition to the traditional *F* values shown in Table 3 for each variable, the results of Newman-Keuls multiple comparisons between the three means are shown in cases where the overall *F* was significant.

The variables shown in Table 3 are grouped together into classes of phenomena. Clearly, the largest differences between the experimental conditions came on the group feeling items and on the disinhibition items. The measures of disinhibition showed differences between the three conditions that were highly significant, and the Newman-Keuls analyses indicated that for these variables, all three groups were significantly different from the others. For the group feeling items, each of the three conditions also tended to be significantly different from the other conditions.

The self-consciousness and loss of identity items also showed differences between groups. The deindividuation group was significantly different from both of the other two groups on two of three key items. Although feelings of anonymity and concern over the evaluation of others did not reach an alpha level of .05, the deindividuation group did score in the predicted direction on these items. The smallest differences between conditions were on the altered state and memory items. It can be seen in Table 3 that most of the altered state items were not significant, although the deindividuation group was most extreme on these variables. For the memory items, the deindividuation group had the worst memory for the statements of the confederates and for cues in the room, but the best memory for the faces of the confederates, which is similar to the pattern found by Diener and Kasprzyk (Note 1). Finally, it can be noted that subjects' recognition of their own statements was almost perfect in each condition.

Analyses for Artifacts

There were several potential problems in the present study, and these should be analyzed. One question concerns the unit of statistical analysis used earlier. Individuals, not pairs of subjects, were employed in the analyses although the pairs of individuals might not be independent, since they could have influenced each other. This seems unlikely, since the majority of the group were confederates, and they set the tone of the group by acting similarly to each other. However, the possibility that subjects within the subject pairs influenced each other was checked by correlating within conditions each factor score for pairs of subjects run together. Thus, correlations for each of the conditions were derived that represented the similarity of the responses of pairs of subjects run together. These correlations were all near zero and averaged .06, revealing that the data for each subject were independent of the other subject's scores.

Another question concerns suspicion. When asked to guess the purpose of the study, fewer than 15% of the subjects had any idea beyond a study of creativity, and only a few subjects guessed anything related to the true purpose. Similarly, when asked about their suspicion of the confederates, the vast majority of subjects checked the choice saying they honestly never suspected any of the confederates. There were virtually no differences between conditions on the suspicion items. The two suspicion measures did not correlate with the number of weeks (rs = .079 and −.069), indicating that suspicion was not increasing during the semester as subjects were becoming more knowledgeable about psychology. This also suggests that leakage about the study into the subject pool was not occurring to any extent, which is consistent with past findings (Diener, Matthews, & Smith, 1972). Finally, the correlations between subjects' factor scores and their suspicion scores were low, ranging from −.06 to .08, with a mean of .01. Thus, there appeared to be low levels of suspicion, and what little suspicion there was did not seem to influence the data.

Discussion

The present results support the importance of the deindividuation construct, which relates social situational factors to lack of self-awareness and in turn relates lowered self-awareness to disinhibited behavior. The factor analysis revealed that characteristics such as lack of self-awareness, lack of conscious planning, group unity, disinhibited behavior, and lack of concern about what others would think of the subject all formed a single central factor. A comparison of factor scores revealed that subjects exposed to the deindividuation manipulation scored significantly higher than the other two groups on this factor. Thus, the two types of analyses converged in suggesting the validity of the deindividuation construct.

It should be noted that there was a significant first-order correlation between disinhibited behavior and lack of self-consciousness. This indicates that less self-aware participants tended to exhibit more disinhibited behaviors. The question arises as to whether low self-awareness caused disinhibited behavior or the reverse. This question cannot be answered with certainty because of the correlational nature of the findings. However, the correlation of −.35 between self-awareness and disinhibition of the initial activity choice (before any activities were done) suggests that the deviant

activity did not cause the lowered self-awareness. We know from the self-awareness literature that persons with lower self-awareness are less likely to adhere to norms, and therefore we can conjecture that the lower self-awareness exhibited by deindividuated subjects could certainly have had some causal role in disinhibiting behavior.

The present findings clearly support Diener's (1979) theory of deindividuation, which integrates the concepts of self-awareness and self-regulation with earlier conceptions of deindividuation. Lack of self-awareness and lack of conscious planning, group unity, and disinhibited behavior did occur together within individuals. Deindividuating conditions also produced these changes in subjects. The negative correlation between self-awareness and behavioral disinhibition also supports the theory of self-awareness (Wicklund, 1975, 1979). According to the theories of self-awareness and deindividuation, lowered self-awareness leads to lessened self-regulation because the person is less aware of behavior–norm discrepancies and less likely to plan for the future. The present results are compatible with these formulations.

The study provides a less clear answer to the second question addressed—whether deindividuation is similar to a lack of self-awareness occurring because of nonsocial causes. The deindividuation group was significantly higher on Factor 1 than the non-self-aware group, which did not differ significantly from the self-aware group. It can be noted that non-self-aware subjects, although somewhat less self-aware than self-awareness condition subjects, did not more frequently report a loss of identity or lower conscious planning. In addition, classification of subjects based on the discriminant function revealed that only a third of the non-self-aware subjects were grouped together with the deindividuation participants. Social causes of lowered self-awareness may be more likely to release dishibited behavior because the person can perform novel or antinormative behaviors and not become self-aware, whereas the person whose attention is focused outward by nonsocial factors can easily focus back on the self when confronted by norm-related choices or a novel situation. It is also possible that a unique characteristic of deindividuation is that the person not only loses a sense of individual identity but also goes along with the direction of group behavior.

The answer to whether deindividuation is accompanied by altered experiences is left uncertain by the present data. The deindividuation group differed significantly from the non-self-aware group on the second factor, which included several altered state items. About 40% of deindividuated subjects answered "yes" to the statement, "Felt like I was in an altered state of consciousness in which my perceptions or thinking were distorted compared to their normal functioning." It should be recalled, however, that a fairly large number of persons in the other groups also reported such experiences (about 25%) and that the differences between groups on these items were not significant in most cases. Thus, more research on this issue is necessary before firm conclusions can be reached.

One additional characteristic that has been proposed as part of deindividuation is a memory decrement (Festinger et al., 1952; Zimbardo, 1970). In the present study the memory for what had been said by others was poorest for the deindividuation group. However, subjects' memory for what they had said was uniformly high across conditions, indicating that even when self-awareness is low, the person can often still remember later what he or she has done. In addition, the deindividuation group had higher memory scores for pictures of the other group members, perhaps because they were more involved with the group. The deindividuated subjects were somewhat poorer at memory for peripheral cues. This pattern suggests that "memory" differences actually result from attentional differences in the various conditions and that deindividuation does not automatically lead to reduced memory or amnesia.

Alternative Explanations

There are a number of alternative explanations for the present results.[2] It is possible that

---

[2] One other alternative explanation for the present findings is in terms of demand characteristics. The major reason to discount a demand characteristics explanation of the findings is that it does not explain

subjects who conformed more to the disinhibited atmosphere in the deindividuated condition simply liked the group more, and they therefore complied with the demands of the setting. It should be noted that the conformity explanation does not contradict the idea of deindividuation. Indeed, compliance or conformity to group behavior in the initial stages of group activity may often set the stage for deindividuation and for the group to thereafter move in increasingly disinhibited directions. However, it does not appear that conformity is the sole explanation for the present findings. First, deindividuation subjects chose more disinhibited boxes immediately after the group manipulation and before they knew what other subjects had chosen. And second, deindividuation subjects showed a variety of responses that are not explained simply by conformity, for example, more frequently reporting a loss of identity, lower self-consciousness, and less conscious planning.

---

why the deindividuation items formed a coherent factor, as predicted by the theory. Another reason to discount this possibility is that few subjects guessed the true purpose of the study, and those few who did responded no differently from those who did not.

Effects of Difficulty and Diagnosticity on Choice Among Tasks in Relation to Achievement Motivation and Perceived Ability

Ursula Buckert
Oberhausen, West Germany

Wulf-Uwe Meyer
Universität Bielefeld, West Germany

Heinz-Dieter Schmalt
Ruhr-Universität Bochum, West Germany

The experiment is a partial replication of a study conducted by Trope. It investigates the effects of two person characteristics (achievement motive and perceived own ability) and two task characteristics (difficulty and diagnostic value about own ability) on choice among achievement tasks. In accordance with the results of Trope, it was found that high-diagnostic tasks were preferred to low-diagnostic tasks, independent of their difficulty. Trope's finding that high resultant achievers choose high-diagnostic tasks over low-diagnostic tasks to a greater extent than low resultant achievers was not replicated. However, the perceived degree of own ability affected choice behavior: When easy and difficult tasks were both high in diagnosticity, subjects high in perceived ability preferred difficult over easy tasks, whereas subjects low in perceived ability preferred easy over difficult tasks. From this latter finding it is concluded that a self-informational conception of choice behavior has to include the subjective probability of success at tasks as a determinant of choice, in addition to objective difficulty and diagnostic value.

According to Atkinson's (1957, 1964) theory of achievement strivings, individuals high and low in resultant achievement motivation differ systematically in their choices of achievement tasks. High resultant achievers will select tasks that are intermediate in subjective probability of success, whereas low resultant achievers prefer to undertake tasks of high or low subjective probability (P_s). These predictions are based on a hedonic conception of achievement-related behavior. It is assumed that the choice of tasks intermediate in P_s maximizes positive affect (pride), prospectively connected with success, for individuals high in resultant achievement motivation, and that the selection of tasks high or low in P_s minimizes negative affect (shame), prospectively connected with failure, for persons low in resultant achievement motivation. In the relevant empirical studies undertaken by Atkinson and his co-workers, P_s is equated with the difficulty of the experimental tasks.

An alternate conception of achievement-related choice was developed by Weiner et al. (1971). This approach, which is based on the principles of attribution theory, explains the assumed differential task selection of the two motive groups in terms of the expected self-informational feedback of an outcome. It is assumed that high resultant achievers are motivated to obtain information about their capabilities; they therefore select tasks of intermediate difficulty because success and failure at these tasks yield the most information about the person undertaking these tasks. On the other hand, low resultant achievers are assumed to be motivated to avoid this information; they therefore select very easy or very difficult tasks. This is assumed because success at easy tasks and failure at difficult tasks (the usual outcomes) yield relatively

little information about one's ability. This lack of self-informational feedback results from the fact that outcomes consistent with social norms lead to causal inferences about the task rather than about the person undertaking the task (Heider, 1958; Kelley, 1967, 1973). Thus, the same pattern of choices for the two motive groups is predicted from Atkinson's hedonic and Weiner et al.'s informational approaches to achievement behavior.

Two recent studies by Trope and Brickman (1975) and Trope (1975) unconfounded the factors that lead to these identical predictions that are derived from Atkinson's achievement motivation theory and Weiner et al.'s attributional conception. These authors argued that the relationship between task difficulty and expected self-informational value, postulated by Weiner et al. (1971), is not universally valid. The informational value also depends on the diagnosticity of tasks, which is operationally defined as the difference in the percentage of success at a given task between individuals high versus low in ability. For example, suppose that 100 people, 50 high in ability and 50 low in ability, first perform Task A and then Task B with the two possible outcomes, success or failure, at each. At each task 40 individuals succeed. The overall probability of success of both tasks then is .40. Suppose further that on Task A 40 from the group high in ability are successful and none from the group low in ability, whereas on Task B 22 out of the high-ability group have success and 18 from the low-ability group. It is clear that success at Task A distinguishes better between persons with different ability levels than success at Task B. Although the overall difficulty of both tasks is equal, Task A is more diagnostic of the ability level of a person than Task B.

Trope and Brickman pointed out that intermediate difficulty tasks are generally, but not necessarily, more informative (diagnostic) than easy or difficult tasks because tasks of intermediate difficulty mathematically can be made maximally diagnostic and therefore are ordinarily more efficient at discriminating between people with high and low ability. The authors conducted an experiment in which the variables, difficulty and diagnosticity of tasks, were independently manipulated. Groups of subjects were given a choice among easy, moderate, and difficult tests. The tasks of each test were highly diagnostic for some groups and low in diagnosticity for other groups. The results showed that tasks of high expected diagnostic value were preferred over tasks of low expected diagnostic value, independent of their difficulty. This result is interpreted by the authors as incompatible with Atkinson's theory because information seeking rather than maximizing positive affect (exhibited by a preference for intermediate difficulty tasks) seems to be the crucial determinant of choice behavior.

In a replication of Trope and Brickman's study by Trope (1975), resultant achievement motivation also was measured. The results again showed that high-diagnostic tasks were generally preferred to low-diagnostic tasks. Moreover, high resultant achievers preferred high over low-diagnostic tasks to a significantly greater extent than low resultant achievers. These results again are viewed by Trope as contradicting Atkinson's theory and giving some support to the position of Weiner et al. (1971) that high resultant achievers strive for ability-relevant information and that low resultant achievers avoid such information. Trope (1975), however, pointed out "that replication studies that employ other measures of achievement motive are definitely needed in order to firmly establish this conclusion" (pp. 1010–1011).

The present experiment is a partial replication of the studies conducted by Trope and Brickman (1975) and Trope (1975). It includes a well-validated German instrument for the assessment of resultant achievement motivation developed by Schmalt (1976). In addition to achievement motivation, the degree of ability that the subjects ascribe to themselves (perceived ability) is introducted here as a further independent variable; several authors have considered perceived ability as an important determinant of the achievement motive (Heckhausen, 1977; Meyer, 1976) or even equated differences in resultant achievement motivation with differences in perceived ability (Kukla, 1972, 1978; Meyer, 1973).

Method

Subjects

Subjects were 104 male students, 16 to 19 years old and attending Grades 11 and 12 of two German high schools (Gymnasium).

Design

The general features of the design and the procedure resembled those employed by Trope and Brickman (1975) and Trope (1975). The study included two experimental conditions with three tests varying in difficulty in each condition (easy ≈.70, moderate ≈.50, difficult ≈.30). In Condition 1, the test moderate in difficulty was high in diagnosticity, whereas the other two tests were low in diagnosticity. In Condition 2, the easy and the difficult test were high in diagnosticity, whereas the moderate difficult test had low diagnosticity. There were 51 subjects assigned to Condition 1 and 53 subjects to Condition 2.

Two other independent variables included in the study were the subjects' resultant achievement motivation and the degree of perceived ability that the subjects ascribed to themselves. Resultant achievement motivation was measured by the adult version of the Need Achievement (n Ach) Grid developed by Schmalt (1976). This instrument includes a series of depicted achievement situations with a fixed set of statements characteristic for hope of success and fear of failure orientation. The statements are taken from Thematic Apperception Test (TAT) scoring codes (Heckhausen, 1967) and are the same for each depicted situation. The subject has to mark those statements that would be characteristic for himself in each situation. The construct validity of the n Ach Grid is documented by a number of findings (see Schmalt, 1976).

Procedure

The experiment was run in groups ranging from 11 to 25 subjects, with each subject receiving a code to guarantee anonymity. First, the n Ach Grid was administered. The subjects then were told that the experimenter would administer a test called the Minnesota Multiphasic Integrative Orientation Test. To create the impression that the test really would be administered and that ability-relevant information could be gained by all subjects, the experimenter pointed out that she would visit the class three times. Subjects were told that in the first phase the test would be explained and that each subject would be given the opportunity to determine for himself the type of test items he would work on approximately 1 week later. In a second phase, they were told, the tasks selected by each individual would be administered. In a third phase, they were told, each subject would be given the opportunity to get information about the test result from the experimenter.

In accordance with the instructions used by Trope and Brickman (1975) and by Trope (1975), the subjects were then given a test booklet indicating that integrative orientation is characterized by being able "to generate new information from previously known information, to generalize, to find with relative ease new solutions to problems." It was emphasized that standard intelligence tests do not measure integrative orientation and that about half the students from high schools comparable in age were high in the ability and half were low. (For the rationale of this procedure, see Trope & Brickman, 1975.) Subjects were then told that the test consisted of three subtests, each consisting of 16 tasks. It was explained that subjects were to choose a total of 12 items and that they were free to decide for themselves how many items from each test they would like to work on.

Instead of leaving the tasks unspecified as Trope and Brickman did, examples of the tasks, supposedly used in the tests, were presented; they were taken from the Intelligenz-Struktur-Test (Amthauer, 1973). Two rows, with five cubes in each, were shown, with each cube carrying different symbols on the three sides presented. The cubes in the two rows were the same, but in the lower row they were turned, tipped over, or both, and had changed their positions in relation to the upper row. It was explained that pairs of identical cubes had to be identified. Following this presentation, subjects had to estimate the degree of their integrative ability on a 9-point scale. The scale was anchored at odd numbers with the following labels: very high (1), high (3), average (5), low (7), very low (9). Up to this point, the instructions were the same for all subjects.

Manipulation of difficulty and diagnosticity. To create the experimental conditions, subjects received different booklets. In these booklets the information about difficulty and diagnosticity was given in the form of bar diagrams that showed the percentage of students high and low in integrative ability who succeeded on the three subtests. The diagrams were accompanied by an explanation: For the high diagnosticity tests, the subjects were told that there was a relatively large difference between the successes of students high and low in integrative ability. Success or failure therefore would indicate the ability level. For low diagnosticity tests, subjects were told that this difference was relatively small, success and failure therefore would not indicate the ability level. Furthermore, the overall percentage of success indicated whether the test was easy, moderate, or difficult. Table 1 gives the reported percentages of success for high- and low-ability students in the two experimental conditions.

Measurement of dependent variables. After the above descriptions, subjects were given another booklet indicating that they were to choose a total of 12 items from the tests. It was stressed that the items selected were to be performed by the subject during the next test session. In the booklets again some short information about difficulty and diagnosticity of the three subtests was presented in the form of bar diagrams. The subjects were then asked to indicate how many items from each test they would like to be given at the next test session with the total number of items selected not exceeding 12. Furthermore, subjects had to indicate the degree of preference for each test in comparison with the other two tests on a 10-point bipolar

scale ranging from very weak preference to very strong preference.

Results

Since the analyses of item selection and preference ratings yielded the same results, the latter are not presented. The mean number of items chosen from each test in Conditions 1 ($n = 51$) and 2 ($n = 53$) is shown in Figure 1. Figure 1 reveals that in both conditions, more items are chosen from the high-diagnostic tests than from the low-diagnostic tests. The means for each test differ significantly between the experimental conditions, easy, $t(102) = 5.34$; moderate, $t(102) = 10.95$; difficult, $t(102) = 4.61$; $ps < .001$.[1] In contrast to the results from the experiments of Trope and Brickman and of Trope, in Condition 2 there was no preference for easy tasks over difficult ones.

To test the effect of the achievement motive on choice, subjects were divided at the median on the Net Hope (NH) scores in groups high (NH ≥ 5, $n = 52$) and low (NH < 5, $n = 52$) in resultant achievement motivation. There were no significant differences in preference between the motive groups. Thus, Trope's finding of a more pronounced preference of high-diagnostic over low-diagnostic tasks in the high than in the low motive group was not replicated.

To examine the influence of perceived ability, which is unrelated to achievement motivation ($r = -.12$), on item selection, groups high (Scale Values 1–4, $n = 56$) and low (Scale Values 5–9, $n = 48$) in perceived ability were separated, with 26 highs and 25 lows in Condition 1 and 30 highs and 23 lows in Condition 2. The mean number of items selected is shown in Figure 2. In Condition 1 there were no significant differences in the mean preferences of the two groups. In Condition 2, however, individuals low in perceived ability preferred easy test items to a significantly greater extent than individuals high in perceived ability, $t(51) = 3.79$, $p < .01$, whereas for the difficult test in this condition the reversed preference pattern is given, $t(51) = 2.27$, $p < .05$. The difference between the groups at the moderately difficult test failed to reach statistical significance, $t(51) = 1.92$. Within the groups high and low in perceived ability, there were significant differences between the experimental conditions at each level of test difficulty (t test, all ps at least $< .05$).

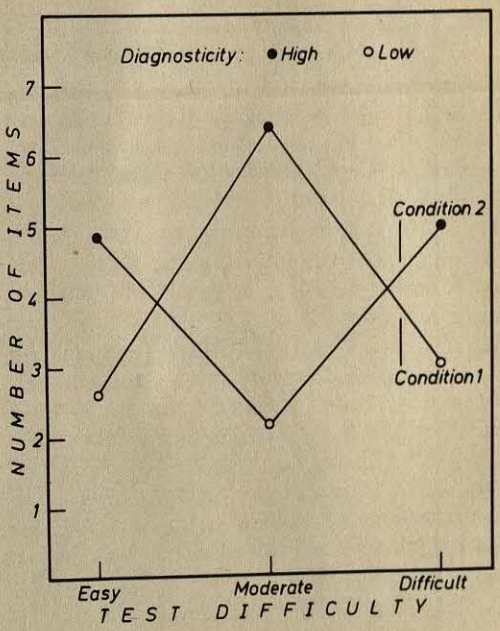

Figure 1. Mean number of items chosen from tests varying in difficulty in two experimental conditions.

Table 1
Percentages of Success Among High- and Low-Ability Students on Three Tests Reported in Two Experimental Conditions

Student ability	Test difficulty: Easy (.70)	Moderate (.50)	Difficult (.30)
	Condition 1		
High	73	75	33
Low	66	28	27
	Condition 2		
High	90	55	51
Low	50	48	10

Note. Criterion values are in parentheses.

[1] A comparison of the means for the tests within each experimental condition was not possible because the number of tasks selected from each test was not independent.

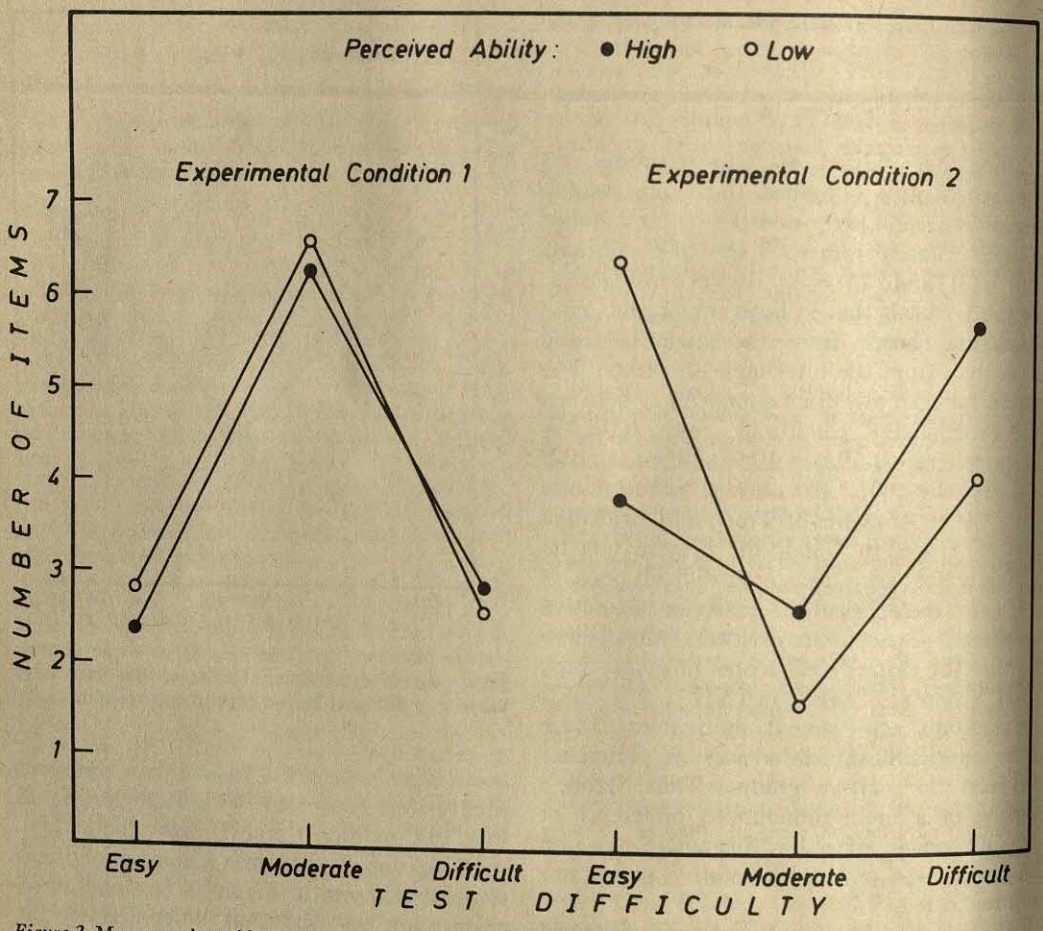

Figure 2. Mean number of items chosen from tests varying in difficulty in two experimental conditions by subjects high and low in perceived ability.

Discussion

The results of this experiment partially replicated the findings reported by Trope and Brickman (1975) and Trope (1975): It was found that high-diagnostic tasks were preferred to low-diagnostic ones, independent of their difficulty. This supports the view that choice behavior is guided by a tendency to attain self-relevant information.

But, in contrast to previous studies, a general preference for easy tasks over more difficult ones was not found. Furthermore, Trope's finding that high resultant achievers choose high-diagnostic tasks over low-diagnostic tasks to a significantly greater extent than low resultant achievers was not replicated. This lack of any differential choice behavior between the motive groups is consistent with the results of Meyer, Folkes, and Weiner (1976), which demonstrated that both high and low achievers selected tasks in a pattern that is best described as normally distributed around the difficulty level of .50.

The disparate results in the experiment reported here and in Trope's (1975) study can scarcely be attributed to the different instruments used for the assessment of the achievement motive in both studies. Meyer et al. (1976) and Trope used the Mehrabian (1969) scale, with Trope finding marked differences in choice between high and low achievers, which was not the case with Meyer et al. Furthermore, in a related study, Starke (Note 1) employed, in accordance with this experiment, the Grid technique. He found that high achievers select tasks that provide ability-relevant feedback, whereas low achievers

select tasks providing ability-irrelevant feedback. Thus, altoghether, it seems clear that individuals high in achievement need—independent of the disparate situational conditions in the experiments—strive for information about their capabilities. However, it remains unclear under what situational conditions individuals low in achievement need strive for or avoid such information.

Another important finding of this study is the difference in choice behavior between subjects high and low in perceived ability. In Condition 2 the high-ability group preferred difficult over easy tasks, whereas the low-ability group preferred easy over difficult tasks, with the easy and difficult tasks being high in diagnosticity. In Condition 1 the two groups correspondingly preferred tasks from the intermediate difficulty test, which is the only test high in diagnosticity in this condition.

This overall pattern of choice is neither completely consistent with Weiner et al.'s (1971) position that choice is a function of task difficulty, nor with Trope and Brickman's (1975) position that choice is a function of the expected diagnostic value of tasks. Thus, there must be at least one other determinant of choice behavior in addition to these two variables. It appears that an informational conception of choice behavior has to include the subjective probability of success at tasks as a determinant of choice. Meyer (1973, 1976) has contended that given tasks with which a person has had a history of involvement, information gain is maximal when P_s at a task equals .50 rather than when the objective difficulty of a task, as defined by the proportion of successful individuals, equals .50. Assume, for example, that Individuals A and B are confronted with a task intermediate in difficulty, both having some familiarity with the general type of tasks. A perceives own task-specific ability to be very high and estimates P_s to be 1.00, whereas B perceives own ability to be very low, estimating P_s at the task to be .00. It is clear that the expected success for A and the expected failure for B prospectively provide no new information concerning their abilities at this intermediate difficulty task, but only corroborate the established ability percepts. Individuals will expect most information about their ability from tasks in which own success and failure are maximally uncertain and whose P_s therefore is .50. Positive results at tasks with higher values of P_s and negative results at tasks with lower values of P_s have less self-informational value, inasmuch as these results either provide information about the difficulty of the task or confirm already established perceptions of own ability.

A number of studies correspondingly show that individuals high in perceived ability estimate the P_s of tasks at all difficulty levels as higher than individuals low in perceived ability (Meyer & Hallermann, 1977; Starke, Note 1; Buckert, Note 2; Schulz, Note 3). Thus, with increasing perceived ability, objectively more difficult tasks should be chosen to get self-relevant information at tasks for which P_s equals .50. Although P_s was not controlled here, it can be assumed, extrapolating from the studies just mentioned, that the perceived ability also influenced P_s: For the high-ability groups, the objectively difficult test (.30) should be nearer to $P_s = .50$ than the easy one (.70), whereas for the low-ability group, the easy test should be nearer to $P_s = .50$. It therefore can be assumed that from tasks equally high in diagnosticity (Condition 2), those are preferred whose subjective probability is closest to .50. Thus, although individuals high and low in perceived ability *phenotypically* select different tasks, *genotypically* they are both striving to attain ability-relevant information.

In sum, it seems false to us to conceive the informational properties of choice in general as a function of task difficulty (Weiner et al., 1971) or as a function of expected diagnosticity, which is usually dependent on task difficulty (Trope & Brickman, 1975). This may be true for situations in which the tasks to perform at are not known to the individual or in which the tasks are unspecified, as in the experiments by Trope and Brickman (1975), Trope (1975), and Meyer et al. (1976, Experiments I and II), or when the individual is completely unfamiliar with the tasks. Under these conditions, when the individual is unable to estimate own task-specific abilities, it might be the most efficient strategy to choose intermediate-difficulty (i.e., highly-diagnostic) tasks to obtain information about one's own ability. But when the tasks are known to the in-

dividual, as in the experiment reported here, and the individual already has an estimate of own ability, which is, however, subjectively not fully valid, then the perceived self-informational value of choice behavior at tasks that the individual perceives as diagnostic, with respect to own abilities, should be a function of P_s with maximal expected information at tasks intermediate in P_s.

Role of Foreseen, Foreseeable, and Unforeseeable Behavioral Consequences in the Arousal of Cognitive Dissonance

George R. Goethals
Williams College

Joel Cooper and Anahita Naficy
Princeton University

Subjects delivered a counterattitudinal speech supporting an unwanted policy. Two groups were given information about the consequences of making the speech before agreeing to make it. One was explicitly informed of the possibility of an unwanted consequence occurring. The second group was given a general description of the consequences that was designed to make the specific unwanted consequence retrospectively foreseeable if made known later. In addition, there was a third group that was told nothing about the consequences of making the speech at the time of the decision to make it. After the speech was delivered, half of the subjects in each group were informed of a specific unwanted consequence of their act and half were given no further information. As predicted, self-justificatory attitude change was found only in the two conditions in which subjects were informed prior to making the speech of the specific unwanted consequence and in the condition in which subjects were given a general description of the consequences beforehand and specific information about the unwanted consequence after the speech. The results are discussed in terms of the relation of personal responsibility to cognitive dissonance arousal.

A series of recent experiments has made it relatively clear that unwanted behavioral consequences that become known to actors only after they have performed a behavior can lead to dissonance-produced self-justificatory attitude change (Cooper & Worchel, 1970; Cooper, Zanna, & Goethals, 1974; Goethals & Cooper, 1972). There is also considerable evidence leading to the conclusion that such consequences produce dissonance only when their occurrence is foreseen at the time of the decision to engage in the behavior (Cooper, 1971).

The latter point, that unwanted consequences must be foreseen if they are to produce dissonance, is consistent with arguments by Cooper (1971), and also Hoyt, Henley, and Collins (1972), regarding the role of personal responsibility in cognitive dissonance. Cooper proposed that counterattitudinal behavior will produce dissonance if the actor feels personally responsible for the consequences of the behavior. Responsibility is accepted if (a) the person had free choice in performing the behavior and (b) the person was able to foresee its unwanted consequences. However, Cooper's analysis does not tell us whether the unwanted consequences must be foreseen or only foreseeable in order for them to lead to the acceptance of responsibility. The distinction between foreseen and foreseeable consequences is an important one, both for psychological processes and legal decisions.

Consider the following example: A man enters a gambling establishment. According to his already existing cognitions, he would find it undesirable to donate his money to the

The authors wish to thank Marie-Claire Kamin and Mark P. Zanna for their help with this research.

Mafia. In the first situation, the person knows full well that the establishment is run by the Mafia and that any loss of money will enter into mafioso hands. We can say that losing money in this situation will result in a *foreseen* consequence. At the other extreme, a person with the same attitudes enters a church to play bingo. He later learns that the "church" was merely a building borrowed from a movie set and that it was, in fact, a front for the Mafia. He, too, contributed money to the Mafia, but this time the consequence was completely *unforeseeable*.

In the middle lies the situation in which the person does not have firm evidence as to who runs the gambling house. When he learns that it is the Mafia who pocketed his money, he may be tempted to say, "I didn't know." However, he may have had to walk past several bodyguards to get into the place; he may have have had to pass the statue of Al Capone; he may have had to whisper a password to a gun-holding stranger to enter the locked room. It can be argued that he certainly could have known that the Mafia received his money, had he given it some reflection. We can say that the consequence in this situation was *foreseeable*. The difference between the last two situations is that in the former, there was no reasonable way in which the person could foresee the consequence of his behavior. In the latter, a reasonable person could have been expected to be aware of the possible occurrence of the consequence.

A more formal set of definitions may be helpful. By foreseen consequences we mean those whose possible occurrence the actors are explicitly aware of at the time of decision. The occurrence of these consequences need only be possible, not definite, for them to be regarded as foreseen. The critical point is that they be in the actors' consciousness as possible occurrences. By foreseeable consequences we refer to those results of behavior that were not in the actors' awareness at the time of decision but that they feel they—or any reasonable person—could have anticipated in light of the information they were explicitly given. That is, these are consequences the actors were not aware of, but feel in retrospect that they reasonably could be expected to have been aware of them. Finally, unforeseeable consequences are those that the actors were not aware of and, furthermore, feel that there was no way that a reasonable person could have anticipated.

In the present article, we are testing the proposition that both foreseen and foreseeable consequences can lead to the arousal of cognitive dissonance. Unforeseeable consequences will not. Moreover, there will be a major difference between the foreseen and foreseeable situations. Past research (e.g., Goethals & Cooper, 1975) suggests that the explicit mention of an unwanted event prior to a decision to act will result in dissonance arousal regardless of whether subjects ever learn if the event took place. Although this is true of a foreseen consequence, we do not expect it to be true of a foreseeable consequence. When the unwanted consequence is not explicitly in an individual's awareness, it can only lead to dissonance arousal if its occurrence is made explicit after the behavior. Only then will subjects be able to think back to whether they could have been reasonably expected to anticipate the occurrence of the consequence.

In the current study, subjects agreed to participate in attitude-discrepant behavior. The degree of foreseeability of an unwanted behavioral consequence was separated into foreseen, foreseeable, and unforeseeable variations. In the foreseen variation, the unwanted consequence was explicitly mentioned to the subjects as one of the events that could occur as a result of their behavior. It was not a definite outcome, but the subject was made directly aware of its possible occurrence. In the foreseeable variation, the events to follow from the behavior were described in general terms at the time of decision. The specific unwanted consequence was not explicitly mentioned, but it was an instance of the general class of consequences that was described. In the unforeseeable variation, no mention was made of anything bearing any relation to the unwanted consequence that was to result from the attitude-discrepant behavior.

In addition, the information that subjects were given following their counterattitudinal behavior was varied. In the *not-informed* variation, there was no further mention of consequences after the subjects performed the behavior. In the *informed* conditions, subjects

were told explicitly that the unwanted consequence definitely was to occur.

It was predicted that self-justificatory attitude change would occur in the foreseen conditions, regardless of whether subsequent information about the occurrence of the consequence was ever given. On the other hand, subjects in the foreseeable variation were predicted to manifest attitude change only in the informed condition. It was expected that when these subjects received specific post-behavioral information of the occurrence of the consequence, they would feel that they could have been aware of it. Finally, subjects in the unforeseeable conditions were not expected to change their attitudes. Regardless of any subsequent information they might receive about the consequence of their behavior, it was expected that they would absolve themselves of the responsibility for those consequences, since they had no way of knowing about them at the time they agreed to their attitude-discrepant act.

Method

Overview

Under the guise of participating in a study on psycholinguistics, subjects delivered a counterattitudinal speech supporting an unwanted policy on campus. One group was explicitly informed of the possibility of an unwanted consequence following the attitude-discrepant act. A second group was given a general description of the consequences of the behavior, designed to make a specific unwanted consequence retrospectively foreseeable. A third group was not told anything about the consequences of the act.

After the counterattitudinal speech was delivered, half of the subjects in each group were informed of a specific unwanted consequence of their act, and half were given no further information. Finally, the subjects gave a rating of their opinion about the issue at hand, after which they were debriefed.

Subjects

Sixty Princeton undergraduates came in response to an advertisement for a psychology experiment. Subjects who asked for more information about the experiment were told that the study was on psycholinguistics.

Procedure

Each subject was run individually by two experimenters. One experimenter conducted the first half of the procedure and the other experimenter the second half. This technique was chosen to reduce the impression management concerns of the subjects. Both experimenters were female. One was a native of France and the other a native of Iran. Both spoke fluent English with quite noticeable French and Persian accents, respectively. This factor played a part in the selection of the cover story and lent it considerable credence.

When the subjects arrived the first experimenter greeted them and explained that the experiment, being conducted in conjunction with foreign language departments, concerned psycholinguistics and was investigating the different linguistic devices used in oral and written communication. It was explained that subjects would either write an essay or give a speech arguing for one side of a particular issue. The experimenter added that an issue was chosen that most students would be familiar with, namely a pending university decision to double the size of the freshman class and therefore over time, the number of undergraduates at the university. The experimenter explained that she knew how most undergraduates felt about the issue and that she had plenty of speeches and essays opposing the plan. Now, she said, she needed some favoring the proposed policy.

At this point the procedure varied for subjects in different conditions. Those in the unforeseeable conditions were simply told that participation in the experiment was voluntary and that now that they had heard what the experiment was about, they could decide whether they wanted to continue. The experimenter emphasized that the choice was theirs and that they could leave immediately and be paid. All subjects agreed to stay.

For the subjects in the foreseen and foreseeable variations, the experimenter explained that she should tell the subjects that several other groups on campus besides the psychology and language departments were interested in the speeches and essays collected in the study. She said that they were interested in things such as the linguistic devices used, the issues raised, and the tactics taken in composing the communications. In the foreseeable conditions the experimenter simply explained that the subject's speech would be sent to one of the interested groups on the basis of a random selection procedure. Then she proceeded to the discussion of free choice. In the foreseen conditions, before mentioning the random selection procedure the experimenter elaborated on the interested "groups" by deliberately reading from a note pad the names and interests of the groups. She stated:

> The groups are first, a group of graduate students in a linguistic strategies seminar (this group is interested in the linguistic devices used in the speeches and essays collected in this study) and second, the debating team. This group is interested in the fact that we have chosen topics that have two sides to them, and have asked for speeches and essays on both sides. Thus the interest of this group lies in the tacks taken by different students in composing the communication. And finally, the board of admissions of Princeton University is also interested in this study, for as I mentioned before, the University is considering an increase to 1,600 in the size of the freshman class.

When the subject had agreed to write the essay, the experimenter led her to another room where the subject was introduced to the second experimenter who was "helping out" with the project and who would record the speech and ask some final questions. The first experimenter said goodbye and left. The remainder of the procedure was conducted by the second experimenter. She gave the subject some paper to make notes on, told the subject to take 5 minutes to prepare a 1-minute speech, and left the room. She returned in 5 minutes and recorded the subject's speech. She began recording by speaking the subject's name and the topic and direction of the speech into the microphone. Then she handed the microphone to the subject who delivered the speech.

After the speeches had been recorded, the experimenter told the subjects that they seemed very persuasive. Then in the foreseen-informed condition, she reminded the subjects that a random process was to be used to determine which of the three other interested groups would get the speech. She asked the subject to look at a letter on the back of the piece of scratch paper, saw that it was the letter "B," and pointed to a chart showing that speeches recorded from pieces of scratch paper with the letter "B" would be sent to the board of admissions.

In the foreseeable-informed condition, the experimenter reminded the subjects that other groups were interested in the speeches and told the subjects what the three groups were, exactly as the subjects in the foreseen group had been told prior to the speech. Then she explained the random assignment procedure and informed the subject that the speech was to be sent to the board of admissions.

In the unforeseeable-informed condition, the experimenter explained to the subjects after the speeches were recorded that there were other interested groups, and so forth. Then the actual groups were identified, the random assignment procedure was explained, and it was revealed to subjects that their speech would be sent to the admissions board.

None of these postspeech events occurred for the subjects in the three not-informed conditions. All subjects then were asked to answer a questionnaire that contained a question asking the subjects to indicate, on an 11-point scale, the extent to which they agreed or disagreed with the idea of doubling the size of the freshman class. When the experimenter gave the questionnaire to the subjects, she explained she had to leave briefly to get another questionnaire. She told the subjects to complete the first questionnaire and put it in an envelope while she was gone. This questionnaire served as the main dependent measure of the study. When the subjects had placed the first questionnaire in the envelope, the experimenter returned with the second questionnaire that contained several questions about the experiment, including how free subjects felt to refuse to participate in the study and a check on the manipulations. The manipulation check asked subjects, on an 11-point scale, whether their speech was to be used for linguistic research only or other purposes as well. After the subjects had completed the second questionnaire, they were fully debriefed, sworn to secrecy, and paid $1.50 for their participation.

Table 1
Means on Question Regarding Uses of Speech

Condition	Foreseen	Foreseeable	Unforeseeable
Informed	10.7_c	10.2_c	10.3_c
Not informed	10.7_c	5.9_b	1.6_a

Note. Higher numbers indicate subjects believed that speech was to be used by "other groups"; lower numbers that speech was to be used for "linguistic research only." Means not sharing a common subscript differ at the 5% level by the Newman-Keuls test.

Results

Effectiveness of the Manipulations

Subjects were asked whether their speeches were to be used for linguistic research only or whether they would also be used by other groups. The means on this measure are presented in Table 1. An analysis of variance showed significant main effects for the informed factor, $F(1, 54) = 60.55$ $p < .001$; the foreseeability factor, $F(2, 54) = 24.36$, $p < .001$; and a significant interaction, $F(2, 54) = 20.34$, $p < .001$. Subjects in all three informed conditions were well aware that the speech would be used for other purposes. In addition, subjects in the foreseen–not-informed conditions knew that the speech would be used for other purposes. Subjects in the foreseeable–not-informed condition were, surprisingly, less aware that the speech would be used for other purposes than subjects in the aforementioned conditions, but more aware than subjects in the unforeseeable–not-informed condition who believed that the speech would be used for research purposes only. The foreseeable–not-informed condition subjects' lesser awareness of other uses of the speech makes sense in terms of their being less fully informed about the other groups interested in the speeches. Overall, the results suggest that the manipulations had their intended impact. In addition, all subjects indicated that they felt free to decline participating in the speech-making task.

Attitudes Toward Increases in Class Size

Subjects were asked whether they thought that the freshman class size should be increased

to 1,600 students. They responded on a scale labeled *strongly agree* (scored 1) and *strongly disagree* (scored 11) at the end points. The results are presented in Table 2. As expected, subjects in the unforeseeable–not-informed group were strongly opposed to an increase in the size of the freshman class. This group, which made a speech but never believed any unwanted consequence would occur, was expected to reflect the prevalent attitude on campus ($M = 10.1$)

An analysis of variance performed on the data of Table 2 resulted in main effects for both the informed and foreseeability factors. Informed subjects evidenced more favorable attitudes toward the proposal than not-informed subjects, $F(1, 54) = 5.85$, $p < .02$. In addition, as the degree of prior awareness of the consequences increased from unforeseeable to foreseen, subjects indicated greater agreement with the counterattitudinal position, $F(2, 54) = 12.26$, $p < .001$. Most important, our hypotheses led to the prediction of an interaction between the two variables. This was supported by the analysis of variance, which found the interaction to be reliable, $F(2, 54) = 3.50$, $p < .05$. A Newman-Keuls analysis summarized in Table 2 adds further support. When the consequences were foreseen prior to the decision to act, subsequent information made no difference in the magnitude of attitude change. Both the informed and not-informed variations evidenced substantial changes in belief toward the proposal. Similarly, when the consequences of the behavior were completely unforeseeable prior to the decision, the level of subsequent information again made no reliable difference in final opinions. However, when the consequences were foreseeable—those that one might reasonably have been expected to anticipate but were not explicitly made known prior to the act—then the level of subsequent information made an important difference. If not informed of the unwanted consequence, foreseeable subjects reported anti-class increase attitudes ($M = 10.2$), but if they were subsequently informed, they demonstrated considerable moderation ($M = 7.4$). The difference between the two foreseeable variations was significant ($p < .05$).

Discussion

The results are supportive of the original predictions. First, when subjects perform an act under conditions of high choice that they realize has the potential to produce unwanted consequences, they show the effects of experiencing dissonance. This is true whether or not the subjects are informed that the unwanted consequence did actually occur. That is, even if subjects are not told the outcome of their behavior, they still show manifestations of dissonance. This latter finding is entirely consistent with previous research (Goethals & Cooper, 1975) suggesting that the mere possibility that one's behavior will produce unwanted consequences is sufficient to produce dissonance if subjects anticipate receiving no further information regarding the final outcome.

Second, if one's behavior produces unwanted consequences that are totally unforeseeable, such consequences produce no dissonance. If a subject performs what appears to be innocuous behavior that later turns out to have unwanted consequences that could not possibly have been foreseen, the subject will not accept responsibility for those consequences and will not manifest dissonance.

Finally, and most importantly, the study has demonstrated that consequences made known to the subject after he or she has performed a behavior can and do produce dissonance if the subject perceives, retrospectively, that they were foreseeable; that is, that he or she could have foreseen that such an unwanted consequence could occur.

One important aspect of these results is that they reaffirm the idea that personal responsibility for consequences is a necessary precondition for dissonance arousal. Furthermore, the study has helped specify under what conditions subjects will accept responsibility. They will accept responsibility if they feel the consequences were foreseeable, in the sense that they *could have been* foreseen by one who was being careful and thoughtful about his or her behavior. Because the consequences could have been foreseen, subjects will feel that they should have foreseen them and are responsible

Table 2
Mean Attitudes Toward Increasing the Size of the Freshman Class

Condition	Foreseen	Foreseeable	Unforeseeable
Informed	7.1_a	7.4_a	9.6_b
Not informed	7.4_a	10.2_b	10.1_b

Note. Higher numbers indicate less favorable attitudes toward increasing class size. Means not sharing a common subscript differ at the 5% level by the Newman-Keuls test.

for the unwanted consequences even though they did not, in fact, foresee them.

It seems as if the subjects in our experiment accepted responsibility for their actions in much the same way that the law assigns responsibility to people whose behavior leads to undesirable consequences. Drivers who seriously harm pedestrians in auto accidents are held responsible by the law consistent with the principles of choice and foreseeability. Assuming that the drivers were driving as they were of their own volition, choice is clearly present. But their lawyers might argue that the outcome was not foreseen, or their clients clearly would have driven differently. However, the consequence was foreseeable. A reasonable man (a well-accepted legal fiction) would have foreseen that driving in this way could lead to a serious accident and injury. That is, drivers can be held negligent (i.e., responsible) even if they did not foresee what would occur, if they should have anticipated what might occur.

The demonstration that dissonance can be produced by behavior that was performed where no unwanted consequences were explicitly foreseen is important in terms of the external validity of dissonance research. Most studies have shown that if subjects are coerced or induced to perform behavior that they know has unwanted consequences, they will experience dissonance. Yet one wonders how often people perform such behaviors in real life. Of course, the inducements and pressures that dissonance experimenters use to elicit compliance are not absent from the real world. Still, it seems that people more often perform behavior not realizing that it will produce negative consequences but subsequently find that it did. They then may feel that they should have known. For example, people may not buy a house if they realize that the roof is going to leak. However, they may find that it does leak and that they neglected to check it before they bought the house. Here the consequence was not foreseen but probably would be regarded as foreseeable, and the people will feel responsible for the situation's having occurred. They should reduce dissonance by believing more strongly in how nice their house is. These kinds of events—people behaving in ways that produce unanticipated but foreseeable events—are probably more common in arousing dissonance than those in which people knowingly behave in ways that bring about unwanted consequences.

Finally, these data are important in relation to the overall understanding of the idea of responsibility and its relation to dissonance arousal. Wicklund and Brehm's (1976) review of the development of the responsibility concept suggests that although choice and foreseeability are necessary for responsibility and thus dissonance reduction, "unforeseen consequences can arouse dissonance under special conditions" (p. 71). The present study suggests one special condition for which the unforeseen consequence is retrospectively foreseeable. This special condition seems to apply to all of the studies reviewed by Wicklund and Brehm that appear to contradict the proposition that foreseeability is a necessary prerequisite for accepting responsibility for behavioral outcomes.

For example, in studies conducted by Pallak, Sogin, and Van Zante (1974) and by Sogin and Pallak (Note 1), subjects participated in a task that involved selecting random numbers. They were told afterwards that their numbers could not be used because of the way they had performed the task. Although they did not know beforehand that their numbers might not be used on the basis of the experimenter's criterion, it was probably forseeable that their performances could be found wanting in some way. Subjects were simply told that their numbers "should be usable." This seems to leave open the possibility that on some basis or other, admittedly unknown, they also might not be usable.

Wicklund and Brehm (1976) discuss a study by Aronson, Chase, Helmreich, and Ruhnke (1974) in which subjects wrote counter-attitudinal essays and were told before or after writing them that their essays would be shown to a persuasible or nonpersuasible audience. There were two other conditions (lie conditions) in which subjects were promised that the essays would not be shown to other people. These subjects also discovered after writing their essays that they would be shown to a persuasible or nonpersuasible audience. Aronson et al. found attitude change in the persuasible audience-after condition, in which they argued that the unwanted consequence was unforeseeable. However, in all conditions of the experiment, subjects were told that their essays would be used "for an attitude change study," and so an element of foreseeability of the unwanted consequence may well have been present. Aronson et al. pointed out that there was greater attitude change in the persuasible audience-lie condition than expected. Perhaps this finding can be explained in terms of this degree of foreseeability. Incidentally, Wicklund and Brehm also noted that this study may have involved foreknowledge on the part of the subjects.

We would like to be able to argue that not only the present study, but also the research reviewed by Wicklund and Brehm (1976), shows conclusively that self-justificatory attitude change does not occur when actors produce unwanted consequences that are truly unforeseeable. We think that a plausible case can be made that retrospective foreseeability of the kind created in the present experiment did exist in all of the studies that were designed to show dissonance effects without foreseeability. However, it is difficult to make this point definitively. Unlike the present experiment, previous studies have been concerned only with a foreseen versus unforeseen distinction rather than a retrospectively foreseeable versus unforeseeable distinction within an unforeseen variation. In examining the procedures of these studies, it may be reasonable to argue that they resemble more clearly our foreseeable variation than our unforeseeable variation, but this argument cannot be drawn conclusively. We believe that dissonance effects have not been demonstrated in conditions in which the unwanted consequences are truly unforeseeable, but further research would be required to support our interpretation of earlier studies.

Focus of Attention, Chronic Expectancy, and Responses to a Feared Stimulus

Charles S. Carver and Paul H. Blaney
University of Miami

Michael F. Scheier
Carnegie-Mellon University

An attentional model of fear-based behavior is proposed and a study that tested the model is reported. It was predicted that among subjects with moderate fear of snakes, heightened self-attention during an approach attempt would cause increased awareness of existing anxiety, followed by one of two courses of events: Subjects who believed that they could do the behavior in spite of their fear were expected to redirect their attention to the behavior–goal comparison and exhibit no behavioral deficit. Subjects who doubted their ability to do the behavior were expected to divert their attention from the behavior–goal comparison and to withdraw behaviorally from the approach attempt. The results of the study support this reasoning. Discussion centers on relationships between the proposed model and previous theory.

Recent approaches to understanding anxiety and anxiety-related behavior have emphasized the role of cognitive processes in such experiences (see, e.g., Sarason, 1972a, 1972b; Wine, 1971). Some of this theorizing, for example, Wine's summary and integration of the literature of test anxiety, has treated attentional focus as an important variable in the fear response. Almost universally, however, direction of attention has been considered only as a response—a reaction to fear-inducing situations. Very little consideration has been given to the *consequences* of shifts in focus of attention.

An exception to this general rule comes from research on fear-based withdrawal that was conducted by Carver and Blaney (1977a, 1977b), investigating the effects of bogus arousal feedback on fearful subjects' approach behavior. In two of those studies (Carver & Blaney, 1977a, Experiment 3; 1977b) subjects were tested who had moderate fear of nonpoisonous snakes, but who varied in their self-rated expectancy of being able to approach, pick up, and hold a snake. Confident subjects were defined as those who believed that they would be able to do those behaviors, even though doing so would cause them some personal discomfort; doubtful subjects were those who reported being not at all sure that they could do the behaviors. Subjects later attempted the behavioral sequence in question while simultaneously receiving bogus heartbeat feedback. For some subjects, the feedback indicated autonomic quiescence, for others it indicated gradually increasing arousal (the heartbeat acceleration was coordinated with the subject's approach behavior). Doubtful subjects (i.e., those with negative expectancies) responded to the arousal feedback by attending less to the comparison between their behavior and their goal (according to self-reports; Carver & Blaney, 1977b) than did subjects in the constant heartbeat control group and by withdrawing earlier in the approach sequence. However, confident subjects (i.e., those with positive expectancies) responded to the arousal

Portions of the material contained in this article were presented at a symposium on "Attention and Social Behavior" at the August 1978 meeting of the American Psychological Association.

feedback by increasing the attention they paid to the comparison between their behavior and their goal and by bringing the one into closer conformity with the other.

Carver and Blaney (1977b) suggested the following interpretation for their findings, based on Duval and Wicklund's (1972) self-awareness theory: An accelerating heartbeat might, as a sign of fear, lead to greater self-focus than a constant heartbeat. This would be consistent with theorizing that holds self-focus to be a response to fear-inducing situations (e.g., Wine, 1971). However, Carver and Blaney further suggested that subsequent behavioral and focus-of-attention differences between confident and doubtful subjects might have resulted from two different modes of responding *to* that self-focus. That is, it has been demonstrated repeatedly in other behavioral contexts that one consequence of self-directed attention is a heightened tendency to conform to salient behavioral standards (e.g., Carver, 1974, 1975; Froming, in press; Gibbons, 1978; Scheier, Fenigstein, & Buss, 1974; Wicklund & Duval, 1971). This is an effect of self-attention that appears to occur whenever such conformity is possible. This phenomenon seemed to Carver and Blaney to be implicit in their findings among confident subjects who had been presented with arousal feedback. That is, these subjects reported greater attention to the behavior–goal comparison than did those presented with constant feedback, and they failed to display any behavioral deficit. These subjects thus seemed to be attempting, successfully, to match their behavior to the salient standard (i.e., picking up and holding the snake).

On the other hand, at least one previous study (Duval, Wicklund, & Fine, 1972) had shown that the realization that one cannot conform to the behavioral standard caused self-focus to enhance behavioral withdrawal. That previous demonstration seemed to Carver and Blaney (1977b) to be consistent with their findings among doubtful subjects. That is, arousal feedback caused doubtful subjects to withdraw earlier from the approach attempt and to report reduced focus on the behavior–goal comparison.

More recent data suggest, however, that Carver and Blaney's (1977b) interpretation of their results was not entirely accurate. Specifically, Fenigstein and Carver (1978) have shown that the presence of a sound identified to subjects as their heartbeats causes increased self-attention, as reflected by performance on a color–word test (cf. Geller & Shaver, 1976) and by increased self-attribution of hypothetical outcomes (cf. Buss & Scheier, 1976; Duval & Wicklund, 1973). More importantly, Fenigstein and Carver's results failed to indicate that an accelerating heartbeat sound leads to greater self-focus than does a constant heartbeat sound. Carver and Blaney's (1977b) interpretation of their findings as reflecting responses to self-focus is thus called into question.

A Sequential Model of Fear-Based Behavior

There is, however, a way to reconcile certain aspects of Carver and Blaney's reasoning with the Fenigstein and Carver (1978) finding. A model of approach and withdrawal that does so, which represents a refinement of Carver and Blaney's (1977b) theory, has been presented elsewhere (Carver, in press) as part of a more comprehensive analysis of behavior regulation. The model (see Figure 1) is described by the following assumptions:

1. When a behavioral standard is salient (in this case, to approach and handle the feared stimulus), self-attention leads to increased attempts to conform behaviorally to the standard. If fear arousal cues never become salient during the approach, this process continues until the task is completed. This would seem to reflect what occurred among Carver and Blaney's (1977a, 1977b) subjects who were presented with a constant heartbeat sound. Those subjects apparently accepted the nonarousal information contained in the feedback as veridical. Thus, although they may have been self-attentive (as is implied by Fenigstein & Carver's data, 1978), their behavior reflected only conformity to the standard.

2. If arousal becomes strong enough to be salient, the approach attempt is momentarily interrupted. This interruption leads to an assessment of the likelihood of being able to continue the behavior. The combination of self-focus plus salient arousal information

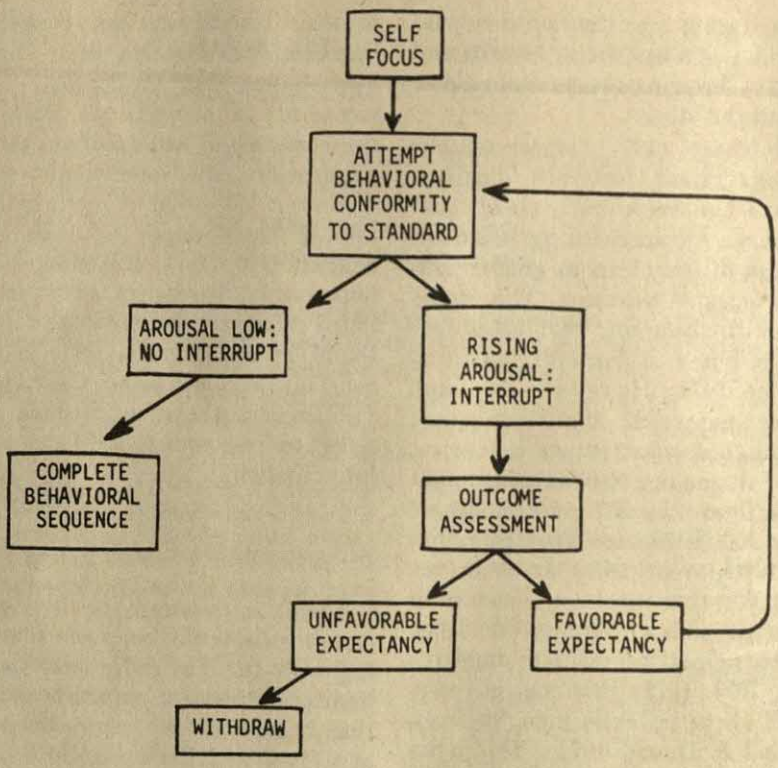

Figure 1. Postulated sequence following self-attention in a fear-provoking behavioral context.

would seem to correspond to the subjective experiences of Carver and Blaney's subjects who had been presented with an accelerating heartbeat.

3. If the outcome of the assessment is a positive expectancy (e.g., if the person judges that he or she can cope with the fear), the result is a return to the matching-to-standard attempt, with perhaps even increased concentration on that attempt (as reflected by self-report focus-of-attention data from Carver and Blaney's, 1977b, subjects). If the outcome is a negative expectancy (if the person thinks that his or her limits have been reached), the consequence is behavioral withdrawal. The expectancy judgment thus is a kind of psychological watershed. All behavioral responses following this judgment seem ultimately to fall into one of those two categories, that is, renewed efforts or withdrawal.

To summarize, in this model the following variables are considered relevant to the understanding of approach behavior in a fear-eliciting situation: the degree of self-focus experienced during the task, the level of anxiety experienced during the task, and one's degree of confidence in probable success at the task. Self-focus initially increases the salience of task completion as one's goal; but if anxiety arises, self-focus also increases one's awareness of the anxiety. The greater the subjective experience of anxiety, the greater the likelihood that one will pause to evaluate one's chances of successful completion. If the resulting expectancy judgment is favorable, the person returns to the approach attempt; if the judgment is unfavorable, the person withdraws. Note that any renewed approach can be interrupted again, later in the sequence, if perceived anxiety increases again.

Present Research

The study reported below was conducted as a test of this model. In this study, dispositional anxiety was held constant and both self-focus and dispositional expectancies were

varied.[1] Specific predictions were derived as follows: Subjects with any substantial degree of chronic fearfulness with regard to some stimulus (e.g. a snake) presumably experience some veridical fear-related autonomic arousal at some point during an attempt to approach that stimulus. There is considerable evidence that in the absence of bogus feedback, experimentally heightened self-focus causes an increase in awareness of one's internal affective states (Scheier & Carver, 1977). Thus we predicted that in a fear-provoking context, heightened self-focus should lead to enhanced perceptions of rising fear arousal among all fearful subjects, regardless of their chronic expectancies. The subjective perception of arousal, above some quasi-threshold, is assumed to cue the self-assessment process. Thus we predicted that the enhanced awareness of anxiety experienced by the self-attentive subjects would lead them to undertake self-assessment earlier in the approach sequence than the less self-attentive subjects, for whom the arousal would be less salient. Subsequent behavioral responses to that early self-assessment, however, should vary with subjects' expectancies. That is, doubtful subjects (those with negative expectancies) should respond by withdrawing earlier in the approach sequence if self-focus is high than if it is low. Confident subjects (those with positive expectancies) should exhibit no such behavioral deficit; if anything, confident subjects should respond with renewed efforts. Thus we predicted an interactive influence of self-attention on subjects' approach/withdrawal tendencies. A similar interactive effect was expected on subjects' self-reports of what they had attended to during the approach attempt.

Method

Subjects

Potential subjects, undergraduates at the University of Miami, completed a two-item pretest at the beginning of the semester. The items required respondents (a) to estimate the amount of anxiety aroused in them by nonpoisonous snakes (very little, slight, moderate, marked, or strong) and (b) to indicate what they thought their response would be to being asked to pick up a nonpoisonous snake ("I'd do it without any discomfort"; "I'd do it, but I'd feel a little queasy about it"; "I'm not at all sure that I'd do it"; or "I'd be too fearful even to try").

Our predictions depended on an interaction between self-attention and expectancies, with chronic fearfulness held constant. To select subjects who differed appropriately with regard to expectancies, we chose persons who reported moderate fear of snakes. Confident subjects were defined as those who also indicated that they could pick up a snake even though feeling queasy about it. Doubtful subjects were those who indicated being not at all sure that they would do it. These were the same criteria for subject selection as were used by Carver and Blaney (1977b).

Subjects completed the experimental procedures described below, in individual sessions several weeks after having completed the questionnaire. Subjects were randomly assigned to either the mirror present or the mirror absent condition by a second experimenter, who had no contact with subjects. The primary experimenter had no knowledge of subjects' pretest scores or of the hypotheses being tested until after the sessions had been completed. Assignment of subjects to conditions led to the following distribution: Each group of doubtful subjects was comprised of 10 males and 6 females, the confident–mirror present group had 10 males and 5 females, and the confident–mirror absent group had 9 males and 4 females.

Procedure

When the subject arrived at the experimental site, he or she was given typed instructions explaining that the study concerned the physical aspects of anxiety. The subject was to attempt to approach, pick up, and hold a live nonpoisonous snake while his or her heartbeat ostensibly was monitored by the experimenter via a microphone. (This explanation and the following procedures were adapted from those of Carver & Blaney, 1977a, 1977b; the microphone was used to make the procedures as similar as possible to those used previously, but the present study did not use any bogus feedback.)[2] Each subject was encouraged to go as far as he or she could (thus establishing approach as the behavioral standard), but the subject was also told that he or she could stop at any point simply by indicating a desire to go no farther.

After reading the instructions, the subject strapped a microphone to his or her chest at a position where he

---

[1] What is critical in the model is the person's *situational* expectancy. However, on the basis of a substantial amount of data from previous research (Carver & Blaney, 1977a, 1977b), we assumed that subjects' dispositional expectancies would provide a good basis for inferring their situational expectancies. The results of the present study lend additional credence to that assumption.

[2] It might be argued that strapping on a microphone would lead to heightened self-attention. However, data from Fenigstein and Carver (1978) indicate that such is not the case.

or she had located a strong heartbeat sound (using a stethoscope provided for this purpose). The subject then was given gloves and was escorted to the test corridor. At the far end of the corridor (which was slightly less than 1 m wide and approximately 4 m long) was a glass cage with a sliding top, standing on a pedestal about .5 m off the floor. Inside this cage was a boa constrictor slightly over 1 m in length. The experimenter reminded the subject that his or her task was to open the cover, reach in and pick up the snake, and hold it until the experimenter said to return it to the cage. After cautioning the subject not to begin until a verbal signal had been given, the experimenter returned to the observation room, ostensibly to turn on the heartbeat recorder.

Self-attention manipulation. Self-attention was varied in this experiment by the presence or absence of a mirror. Evidence that this stimulus does increase self-focus has been discussed at length elsewhere (Carver & Scheier, 1978). For subjects in the mirror absent condition, the corridor was generally featureless. For subjects in the mirror present condition, however, a .5 m × .75 m wall mirror had been hung behind the cage at approximately chest level. The angle of the mirror gave the subject a view of his or her face and shoulders; the snake, however, was not visible in the mirror at any point except the final stage of the approach task (discussed later). In the mirror present condition, before leaving the subject the experimenter pointed out the mirror's presence, indicated that it was part of the experiment, and said that its purpose would be explained later. No subject ever expressed concern or suspicion about the mirror's presence, either at that point or during postexperimental debriefing.

It will be noted that this method of introducing a self-awareness manipulation differs from usual procedures. Typically, the mirror is treated as belonging to a different experiment (e.g., Carver, 1974, 1975) or as being necessary for a subsequent task (e.g., Wicklund & Duval, 1971). We decided to point the mirror out to subjects in the present context, however, for the following reason: A live snake is an attention-attracting stimulus even for people who are not afraid of snakes. Inasmuch as all of the present subjects had reported being moderately fearful of snakes, it seemed likely that they would be very attentive to the snake's presence while in the test corridor. This would tend to make the mirror less salient as a stimulus, thus minimizing its impact on subjects. (See Scheier et al., 1974, for a further discussion of the role of stimulus salience in effectiveness of self-attention manipulations.) For this reason, it was decided to draw subjects' attention explicitly to the mirror as a part of their behavioral context.[3]

Approach task. After the experimenter returned to the observation room, he called to the subject to begin approaching. Nine levels of approach had been predefined: (1) the subject's appearing in the experimenter's view, (2) coming to within 6 inches (15 cm) of the cage, (3) touching the cage, (4) putting a hand inside the cage, (5) touching the snake, (6) grasping the snake, (7) lifting the snake a few inches, (8) lifting it from the cage, and (9) holding it for 15 sec. Each subject's approach score was defined as the highest level that he or she attained.

After the subject had completed the approach task or had indicated an unwillingness to continue, the experimenter told the subject to return to the other end of the corridor. The subject then was escorted to the original room, where he or she was given a postexperimental questionnaire, then debriefed and dismissed.

Postexperimental Measures

The postsession questionnaire contained several items intended to gain indirect evidence on hypothesized mediating processes. (With one exception, noted later, all of these questions were answered on 7-point scales anchored with "none at all" and "very much.") The first item, bearing on the subject's awareness of affect, was "How much anxiety did you experience in the presence of this snake, as indicated by your bodily arousal?"

The presence of noticeable affect was expected to lead to a self-assessment process. This process should be reflected by a momentary sense of concern as to whether one could do the behavior in question. Thus a second question posed to subjects was "When you were approaching the snake, how much did you notice a momentary sense of inadequacy and fearfulness?"

The following three items were included to try to determine what subjects' attention had been focused on during the approach attempt: "When you were approaching the snake, how much attention were you paying to your 'chronic' level of fearfulness toward snakes?"; "When you were approaching the snake, how much attention were you devoting to assessing whether or not your bodily arousal was increasing?"; and "When you were approaching the snake, how much attention were you paying to your goal—that is, picking up and holding the snake—and how well you were doing compared to that goal?"

Finally, subjects were asked to rate their general level of fearfulness toward nonpoisonous snakes. This

---

[3] It might be argued that this experimental setting has the particular demand characteristic of reminding subjects that they had previously made a prediction about whether or not they could do the approach task. If this were the case, however, one would expect a behavioral difference between confident and doubtful subjects in both mirror present and mirror absent conditions. As will be detailed later, this did not occur. It might be argued, on the other hand, that heightened self-focus makes subjects more sensitive to preexisting demand characteristics. This is evidence from three separate studies, however (Gibbons, Carver, Scheier, & Hormuth, in press; Scheier, Carver, & Gibbons, in press), that self-focus can exert precisely the opposite influence. The nature of demand characteristics in this type of research is an interesting theoretical problem, but full treatment of the problem is beyond the scope of this article.

tem was identical to the first pretest item and had the same five response options as had the pretest item.

It will be noted that all of these self-report data were collected after the behavioral task had been completed. Thus results on these items should be interpreted with some caution.

Results

Awareness of Affect

An analysis of variance was conducted on self-reported degree of anxiety felt in the presence of the snake (see Table 1) to determine whether the manipulation of self-focus had increased subjects' awareness of their bodily anxiety responses.[4] This analysis, as predicted, yielded only a main effect for self-awareness condition, $F(1, 52) = 9.62$, $p < .004$, with greater anxiety being reported by subjects in the mirror present than in the mirror absent condition. Group comparisons using the error term from the overall analysis of variance (Winer, 1962, p. 65ff.) indicated that this effect was most reliable among doubtful subjects, $t(52) = 2.92$, $p < .01$, the comparable comparison not attaining significance among the confident subjects ($t = 1.41$, *ns*).

Table 1
Self-Reported Anxiety Experienced in the Presence of the Snake, Self-Reported Momentary Sense of Inadequacy and Fearfulness During the Approach Task, and Actual Level of Approach Toward the Snake

Group	Condition: Mirror present	Condition: Mirror absent
Self-reported anxiety[a]		
Confident	4.33	3.46
Doubtful	5.25	3.56
Self-reported sense of inadequacy[a]		
Confident	4.20	3.85
Doubtful	5.38	3.63
Approach behavior[b]		
Confident	8.47	8.23
Doubtful	6.38	8.31

[a] Larger numbers indicate greater anxiety and felt inadequacy. [b] Larger numbers indicate greater approach.

It was expected that awareness of anxiety and consequent self-assessment would be reflected in self-reports of having experienced a momentary sense of "inadequacy and fearfulness." An analysis of variance of those data (see Table 1) revealed that again there was a significant main effect for self-awareness condition in the expected direction, $F(1, 52) = 6.05$, $p < .02$. As with the anxiety self-reports, this effect was most reliable among doubtful subjects, $t(52) = 2.85$, $p < .01$; among confident subjects, $t < 1$. No other component of this analysis was statistically significant.

Approach Behavior

It was predicted that heightened self-focus would interact with subjects' expectancies of being able to do the approach task, such that heightened self-attention would cause earlier withdrawal among doubtful subjects but not among confident subjects. An analysis of variance of approach scores yielded a marginally significant interaction, $F(1, 52) = 3.67$, $p < .06$, of the expected form (see Table 1). Subsequent comparisons indicated that doubtful subjects withdrew reliably earlier in the approach sequence when the mirror was present than when it was absent, $t(52) = 2.48$, $p < .03$. The approach scores of the confident subjects were unaffected by the presence of the mirror, however.

There was a considerable range of within-cell variances on the approach measure. Although this diversity was not sufficient to render an analysis of variance entirely inappropriate by F_{max}, we judged it desirable to gain additional information on approach scores through a nonparametric test. Therefore, a comparison between approach scores of the two doubtful groups was conducted by means of a Kruskal–Wallis "analysis of variance by ranks" (see, e.g., Hays, 1963, p. 637ff.). When adjusted for ties in rank, this test also indicated that the scores of these groups did differ as predicted, $H' = 10.04$, $p < .01$.

[4] All analyses reported here included sex of subject as a variable. Because there was only one significant effect involving sex in the results of the study, however, data presented in all tables have been combined across gender.

Table 2
Self-Reports of Attention Paid to Chronic Level of Fearfulness, Self-Assessment of Bodily Arousal, and Behavior–Goal Comparison

Group	Condition: Mirror present	Condition: Mirror absent
Chronic level of fearfulness		
Confident	4.67	4.23
Doubtful	4.81	3.56
Assessing degree of bodily arousal		
Confident	3.60	4.69
Doubtful	4.31	3.13
Behavior–goal comparison		
Confident	5.93	5.62
Doubtful	5.06	6.06

Note. Larger numbers indicate greater attention.

Focus of Attention

Three postexperimental items had been included to assess subjects' recollections about what they had focused their attention on while attempting the approach task. Analysis of subjects' self-reports of attention paid to their chronic level of fearfulness toward snakes yielded no significant difference among subject groups (Table 2), with only the self-awareness main effect component approaching significance ($p = .10$).

An analysis of reports of attention paid to assessing whether or not bodily arousal was increasing (see Table 2) yielded two interactions. Of greatest interest was the interaction between pretest group and self-awareness condition, $F(1, 52) = 5.72$, $p < .02$. This interaction indicated that confident subjects tended to report devoting less attention to assessing their arousal when their approach had occurred in the presence of a mirror than if there had been no mirror and that the opposite tendency had occurred among doubtful subjects. Neither of these tendencies was significant by itself, however (ts = 1.56 and 1.81, respectively). In addition, there was an unanticipated Sex × Pretest interaction, $F(1, 52) = 10.99$, $p < .003$, of the following form: Confident males (overall) reported devoting greater attention to assessing arousal than did confident females, $t(52) = 2.18$, $p < .05$, and doubtful males (overall) reported devoting less attention to assessing arousal than did doubtful females, $t(52) = 2.64$, $p < .05$. We have no ready explanation for this gender interaction.

Analysis of self-rated focus on the behavior-goal comparison (see Table 2) revealed an interaction between pretest group and self-awareness condition that approached significance, $F(1, 52) = 3.12$, $p < .08$. In line with previous findings (Carver & Blaney, 1977b), confident subjects tended to report more attention to this comparison, and doubtful subjects reported less attention, when the mirror had been present than when it had been absent. The fact that this interaction took a form opposite to that of the Self-Awareness × Pretest group interaction on attention devoted to assessing arousal suggests that directing attention to the behavior–goal comparison and directing attention to assessing arousal might be complementary processes. When self-rated attention to the behavior–goal comparison was reanalyzed as a proportion of the total attentional focus reported by subjects, the Self-Awareness × Pretest group interaction did achieve an acceptable significance level, $F(1, 52) = 4.62$, $p < .04$. Subsequent comparisons indicated that doubtful subjects in the mirror present condition reported having paid proportionally less attention to the behavior–goal comparison than did doubtful subjects in the mirror absent condition, $t(52) = 2.40$, $p < .04$; the opposite tendency among confident subjects was not reliable ($t < 1$). However, the overall correlation between these two self-reports was quite low ($r = -.10$). This casts some doubt on the notion that the two represent mutually exclusive responses among our subjects.

These analyses of variance all used self-awareness condition as a predictor of the objects of subjects' attention. It is also informative to examine briefly the relationship between perceived anxiety and those objects of attention. Among confident subjects, awareness of anxiety did not predict how much attention was devoted to searching oneself for arousal cues, $r(28) = -.07$; among doubtful subjects, in comparison, there was a clear positive relationship between these variables,

$r(32) = .38$, $p < .02$. These correlations differed reliably from each other ($z = 1.71$, $p < .05$, one-tailed). Additionally, confident subjects displayed a weak but positive relationship between perceived anxiety and attention devoted to the behavior–goal comparison, $r(28) = .19$, $p = .16$, whereas these variables were inversely related among doubtful subjects, $r(32) = -.28$, $p < .06$. These two correlations also differed significantly from each other ($z = 1.65$, $p < .05$, one-tailed). This overall pattern of correlations is quite consistent with our reasoning and with the results of the above analyses of variance.

Postsession Fear

An analysis of subjects' postexperimental ratings of their general levels of fearfulness toward nonpoisonous snakes revealed only a marginally significant tendency for doubtful subjects to report more fearfulness ($M = 3.34$) than confident subjects ($M = 2.82$), $F(1, 52) = 3.21$, $p < .08$. These means represent deviations of .34 and −.18, respectively, from the pretest levels of self-report fearfulness. Correlational analysis provided some evidence that these slight shifts in general fear of snakes were mediated by subjects' observations of their autonomic and physical behavior during the approach task. That is, postsession fearfulness was positively correlated with self-reports of perceived anxiety during the approach task, overall $r(60) = .55$, $p < .001$, and was negatively correlated with actual approach level, overall $r(60) = -.63$, $p < .001$.

Discussion

The results of this study were quite consistent with our hypotheses. According to subjects' self-reports, heightened self-focus led to overall increases in awareness of anxiety-based arousal and in momentary sensations of fearfulness and inadequacy. On the other hand, *behavior* was not directly influenced by self-focus, but rather by self-focus in interaction with expectancies. That is, doubtful subjects withdrew earlier in the approach sequence when self-focus was heightened than when it was not, but no such deficit was exhibited by confident subjects. Self-focus also exerted an interactive influence on the self-reported content of attention during the approach attempt. Confident subjects, though aware of fear, apparently responded to that awareness by attempting to divert their attention from internal fear indices to their behavioral goal. In effect, they showed evidence of increased attempts to match their behavior to the salient standard, even though the approach task quite obviously placed a ceiling on behavior.[5] Doubtful subjects, in contrast, reported increased focus on assessing their bodily arousal and decreased focus on the behavior–goal comparison as functions of heightened self-awareness. These cognitive effects were consistent with the doubtful subjects' early withdrawal from the approach attempt. In sum, the results fit the pattern that had been predicted. Moreover, all of these findings conceptually replicate previous results of Carver and Blaney (1977b).

It is worthy of some additional note that subjects' self-reports of their fearfulness did not allow prediction of their behavior in this task. Our subject groups did not differ from each other in their ratings of their chronic fearfulness of snakes. Yet they differed behaviorally from each other. The ratings of chronic fearfulness were validated to some degree by the finding that reports of situationally experienced fear did not differ reliably between the pretest groups (Table 1). But self-reported fear—even this situational fear—simply did not allow accurate prediction of behavior. Nor did even the self-reported expectancy difference between subject groups predict behavior accurately, except when self-focus was heightened. Apparently these expectancies were utilized by subjects only when attention was self-directed. This pattern of findings is exactly as would be predicted by the sequential analysis presented in the introduction of this article.

---

[5] Enhanced behavioral conformity is somewhat difficult to observe in this context because the desired behavior is clearly prescribed and because there is such a ceiling on performance. However, as discussed in the introduction, heightened conformity to standards as a function of self-attention has been demonstrated previously many times in other contexts (e.g., Carver, 1974, 1975; Scheier et al., 1974; Wicklund & Duval 1971).

The present theory and research have a number of other theoretical implications that deserve mention. The fact that our model is framed in terms of expectancies invites a comparison between it and Bandura's (1977) recent analysis of fear-based behavior. There are some similarities between these models, but there are differences as well.[6] According to Bandura, expectancy judgments make use of several sources of information: the person's prior performances in similar behavioral situations; vicarious experiences, such as the observation of the behavior of another person in the situation; concurrent verbal persuasions, such as externally provided suggestions or self-instructions; and present arousal perceptions. This position on the contribution of arousal perceptions to expectancies was qualified elsewhere (Bandura, Adams, & Beyer, 1977) by noting that attributional considerations play a role in the perceived meaning of the arousal. However, there still appears to be a difference between Bandura's position and ours with regard to the role assumed for arousal perceptions. Our model and the data from the present study suggest that arousal perceptions may cue an assessment process, but that the outcomes of that assessment (expectancy judgments and eventual behavior) depend largely on the other sources of information.[7]

It should be noted, however, that we dealt here with an approach task of only moderate difficulty, which in turn produced only moderate levels of anxiety. It is conceivable that at extremely high levels of arousal, perceptions of autonomic activity can eventually have an impact on the behavior of even confident persons via changes in their expectancies. Indeed, a hint of this more complicated function of arousal perceptions may be contained in the present finding that post-session self-rated fear of snakes was influenced by the anxiety cues that had been perceived during the approach attempt as well as by the level of approach attained. Perhaps subsequent expectancies might also have been altered by one or the other of these sources of information.

One final point should be addressed briefly. A mirror was used to heighten self-attention in this experiment because it has been widely accepted as the "purest" manipulation of self-focus, that is, the least contaminated by other influences. For example, the presence of a videotape camera may raise in a subject's mind the implication that unknown others either are observing now or may observe later. It will be noted, however, that the use of a mirror to induce self-attention in a fear-arousing context leaves open the possibility that any consequent heightened awareness of fear may occur via facial cues rather than internal fear cues. Although this possibility cannot be entirely discounted in the present study, other research (Scheier & Carver, 1977) indicates that enhancement of emotional experience occurs among subjects high in the disposition to be self-attentive as well as among subjects confronted with a mirror manipulation. This convergence of evidence suggests that the primary influence of the mirror, even in an emotional context, is to remind the person of himself or herself. This reasoning also suggests, however, that an important direction for future research will be to test our model's predictions by means of individual differences in self-attention.

---

[6] There are also some similarities between both of these models and Stotland's (1969) analysis of "hope."

[7] Other more subtle conceptual differences between our analysis and that of Bandura are discussed elsewhere (Carver, in press).

Sharing Secrets: Disclosure and Discretion in Dyads and Triads

Ralph B. Taylor
Center for Metropolitan Planning and Research
Johns Hopkins University

Clinton B. De Soto and Robert Lieb
Johns Hopkins University

To develop a more comprehensive picture of the variables that influence disclosure patterns, the impact of group size on sharing secrets was explored. Given Derlega and Chaikin's suggestion that the existence of a closed dyadic boundary is a prerequiste for intimate self-disclosure, it was hypothesized that subjects would be more willing to disclose intimate information in a dyad than in a triad. The results of Experiment 1, which used a role-playing methodology, confirmed the hypothesis. The main effect of group size was observed over a range of roles and items of information. In addition to the main effect, group size interaction effects also indicated that the difference between dyad and triad disclosure rates increased with more intimate items of information and with more intimate roles. These interaction effects suggested that the importance of a closed dyadic boundary depends in part on the expected confidentiality of the interchange. In Experiment 2 the conversations of groups of acquaintances were recorded and rated for intimacy. As predicted, the conversations of dyads were more intimate than those of triads. Suggestions for understanding the intimate quality of dyads are discussed.

Self-disclosure is a topic that has recently generated an enormous amount of research (cf. Cozby, 1973), and substantial support for what Jourard (1971) called the "dyadic effect: disclosure begets disclosure" (p. 66) has been obtained. Two hypotheses—modeling and social exchange—have been offered to explain this effect. The latter hypothesis has received the lion's share of empirical support (Certner, 1973; Davis, 1976; Davis & Skinner, 1974; Derlega, Harris, & Chaikin, 1973; Ehrlich & Graeven, 1971; Jones & Archer, 1976; Worthy, Gary, & Kahn, 1969), and reciprocity has become a dominant theme in self-disclosure research.

However, several limitations preclude drawing conclusions on the generality of reciprocal disclosure. Research has been conducted largely with pairs of strangers, and these interactions may not be prototypical of interactions between acquaintances or friends (cf. Derlega, Wilson, & Chaikin, 1976).[1] Second, almost all disclosure research has been conducted with dyads, and little is known about disclosure patterns in larger groups. For example, when interacting with more than one other, a person may find it difficult to maintain reciprocal disclosure vis-à-vis each other person in the group.

The term dyadic effect seems to suggest that there is something special, apart from reciprocity, about disclosure in dyads. For example, dyads may be more intimate because each person has the undivided attention of the other and can give undivided attention to the

Portions of this research were presented at the meeting of the Eastern Psychological Association in New York, April 1976. This research was conducted while the first author was supported by a predoctoral fellowship from Johns Hopkins University.

other. Although this interpretation of the dyadic effect has intuitive appeal, the little work that has been conducted does more to undermine than support this appeal. Rubin (1976) found that the presence or absence of a third party had no influence on subjects' responses to disclosures by an experimenter. Spinner (Note 1) in his laboratory experiment also found no main effect of group size on depth (intimacy) of disclosure. Drag (1969) found that the two-person discussion groups self-disclosed more than eight-person groups but not more than four-person groups. Group size interaction effects have indicated that people may disclose more or less readily in groups larger than dyads, depending on the composition of the audience (Chelune, 1976) and the mode of communication (Spinner, Note 1).

In sum, although results are mixed, evidence suggests that disclosure patterns in dyads, as compared to other groups, are not unique. Nonetheless, before concluding that there are no effects of group size on depth of disclosure, group size as a source of social influence should be examined.

Blake (1958, p. 229) has suggested that situational sources of social influence include both (a) the "central stimulus" or the "immediate focus of attention" and (b) "context" factors. Group size qualifies as a context factor. In a self-disclosure situation, the recipient of information is the central stimulus. Research has indicated that recipient characteristics such as physical attractiveness (Brundage, Derlega, & Cash, 1977) and a reflective or aggressive style (Ellison & Firestone, 1973) do influence disclosure patterns.

Context factors have received little attention in self-disclosure research, although they can be influential. For example, Johnson and Dabbs (1976) and Rubin and Shenker (1978) both observed that proximity influenced amount of disclosure on low- and medium-intimacy topics.

We wished to further investigate the relationship between group size and disclosure patterns, since (a) context factors in general may exert a widespread influence on social behaviors (Blake, 1958) and (b) group size has been established as a potent influence of social interaction (Bales & Borgatta, 1955; Hackman & Vidmar, 1970; O'Dell, 1968; Slater, 1958; Thomas & Fink, 1963). Exploration of the relationship between group size and self-disclosure uncovers two relevant theoretical considerations. First, Derlega and Chaikin (1977) have suggested that self-disclosure may be viewed as an interpersonal boundary regulation process (Altman, 1975; Altman & Taylor, 1973) and that a precondition of intimate disclosure is the existence of a closed dyadic boundary, that is, "a boundary within which it is perfectly safe to disclose to the invited participant and across which the self-disclosure will not pass" (p. 104). The importance of a closed dyadic boundary has been alluded to before. Simmel (see Wolff, 1950) suggested that dyads have a special quality of intimacy that is not present in larger groups, and thus, dyads could share secrets more often and with more security.

The second theoretical consideration is the layperson's perception of disclosing. De Soto (1960; De Soto & Kuethe, 1959) found that "confides in" was perceived as a pair-forming relationship in contrast to "likes," which was perceived as a group-forming relationship. Confides in was viewed by subjects as symmetric and nontransitive or "essentially a pair-wise interchange" (De Soto & Kuethe, 1959, p. 193). This view of disclosing is congruent with the notion of a closed dyadic boundary.

To test Derlega and Chaikin's (1977) suggestion that a closed dyadic boundary is a prerequisite for intimate disclosure, self-disclosure between acquaintances was examined in dyads and triads. Since a closed dyadic boundary does not exist in a triad, we hypothesized that subjects would be less willing to make intimate disclosures in a triad than in a dyad. Although our hypothesis may seem intuitively obvious to some, it is important to bear in mind that previous research has by and large failed to yield main effects of group size on intimacy of disclosure.[2]

---

[2] Predictions contrary to ours might be drawn from a deindividuation perspective (Diener, Fraser, Beaman, & Kelem, 1976; Zimbardo, 1969), which suggests that the presence of a group serves as a releaser for certain behaviors. Contrary predictions could also be drawn from a sensitivity training or encounter group perspective, which is based on the working assumption

We also expected, in light of Chelune (1976) and Spinner (Note 1), that dyad/triad differences in disclosure rates would increase when more confidential interchanges were expected.

Although intimate disclosures between strangers can be elicited, we decided to focus on intimate disclosures between acquaintances. Given that intimate interchanges occur more frequently between acquaintances than strangers, this focus might enhance the ecological validity of the results.

Experiment 1

Method

Subjects. A specially designed self-disclosure questionnaire, described later, was administered to 21 undergraduate volunteers enrolled in psychology courses at Johns Hopkins University and Towson State University.

Procedure. To manipulate group composition and information content in a controlled fashion, a role-playing technique was used. Willingness versus reluctance to disclose was measured. Subjects were asked to predict how they would behave in hypothetical situations, not how they had behaved in past situations, to assure similarity of situations across subjects. Items contained specific information rather than general topics.

Six items of information were presented on separate pages of the questionnaire with individual roles or pairs of roles listed underneath. The subject was asked to rate how quickly he/she would disclose the item to occupants of various roles or pairs of roles. Each item was encountered twice in the questionnaire—once to assess disclosure to single roles and once to assess disclosure to pairs of roles. The instructions exhorted subjects to think of particular individuals that they knew to fill each role. Disclosure was assessed across several role pairs (sister and best friend of the opposite sex, boy/girlfriend and best friend of the same sex, two liked professors, and acquaintance and roommate) to assess the generality of any effects of group size. Role pairs were chosen on the basis of pilot subjects' suggestions about what role pairs they would be likely to encounter in everyday settings. Finally, disclosure was assessed across six items of information (see Table 1).[3]

A four-category scale ranging from 1 ("I will tell the person [them] as soon as I see him or her [them]") to 4 ("I will probably never tell the person [them]") was used to measure disclosure. Questions concerning disclosure to pairs of individuals were presented separately from those concerning disclosure to single individuals. Order of presentation was randomized across subjects and order of items was randomized within each type of question. At the end of the questionnaire, subjects rated the intimacy of each item of information and the closeness of their relationship with occupants of each of the specific roles.

Results and Discussion

The analysis of variance used a 2 × 4 × 6 (Group Size × Role Pairs[4] × Information) within-subjects factorial design. Although the use of a repeated measures design may possibly have aroused subjects' suspicions, in debriefing no subjects expressed any awareness concerning the group size hypothesis.

The hypothesized main effect of group size was observed, $F(1, 20) = 11.4$, $p < .005$, ($\hat{\omega}^2 = .01$). Subjects indicated that they would be more reluctant to disclose in a triad than in a dyad (see Table 1). This main effect was qualified by two interactions.

A modest though significant Group Size × Information interaction occurred, $F(5, 100) = 2.5$, $p < .05$ ($\hat{\omega}^2 < .01$). The difference in dyad versus triad disclosure rate increased as the intimacy of the information increased (see Table 1). (The rank-order correlation between dyad versus triad disclosure rate and intimacy ratings of the items was .74.) This interaction further supports the hypothesis. As the information under consideration became more intimate, the triad, in comparison to the dyad, was perceived as a less appropriate disclosure setting. Furthermore, relative reluctance to disclose in a triad was a general phenomenon, since it occurred with five out of the six items of information.

Also, a significant Group Size × Role Pairs interaction was obtained, $F(3, 60) = 4.4$, $p < .01$ ($\hat{\omega}^2 = .01$). The difference in dyad versus triad disclosure rate increased as the intimacy rating of the role pairs increased. There was a perfect rank-order correlation

that people are willing to reveal intimate information while in a sizable group.

[3] Only negative items were used, since pilot subjects quickly disclosed items of positive information, regardless of group size or group composition. Although Jones and Wortman (1973) have pointed out that disclosure of positive information can pose problems for the discloser (e.g., being perceived as a bragger), in our samples this was not the case.

[4] To determine disclosure to a role pair when the members of the pair were encountered individually, the mean of the disclosure rate to the two individuals was used.

Table 1
Relationships Among Group Size, Disclosure Rates, and Information in Experiment 1

Information	Intimacy rating	Disclosure rate	
		Dyad	Triad
You have lost a large sum of money from your wallet	3.29	2.24	2.21
You have been rejected from the college or graduate school of your choice	5.14	2.13	2.21
During vacation you got into a car accident due to excessive speed and the person who was with you suffered a broken leg	5.19	2.32	2.63
Your parents are getting divorced	6.66	2.40	2.71
Your brother has been committed to a mental hospital	7.29	2.72	2.98
You have discovered that you have incurable leukemia	7.29	2.89	3.24

Note. On intimacy ratings, a higher score indicates a more intimate item; on disclosure rates, a higher score indicates a slower disclosure rate (i.e., more reluctance to disclose).

between these two measures. Although it was based only on four pairs, this correlation does strongly suggest that a triad, compared to a dyad, became a less appropriate setting for disclosure when the individual was interacting with more intimate contacts.[5]

Consistent with prior self-disclosure research (Derlega & Chaikin, 1975; Jourard & Lasakow, 1958), main effects for role pairs (information was revealed more quickly to more intimate role pairs) and information (more intimate information was disclosed less readily) and a Role Pairs × Information interaction (difference in disclosure rate to acquaintance and roommate and to two liked professors decreased as the intimacy of the items increased) were obtained (all ps $< .001$, ω^2s $= .22, .07$, and $.01$, respectively).

As predicted, subjects thought they would be more reluctant to disclose intimate information in a triad than in a dyad. This main effect and the group size interactions lend support to Derlega and Chaikin's (1977) suggestion concerning the importance of a closed dyadic boundary. Furthermore, the group size interaction effects, although small in terms of magnitude, do suggest that the presence of a closed dyadic boundary became more important as the expected confidentiality of the interchange increased.

Experiment 2

The results of Experiment 1 are limited in that they were based on a role-playing methodology. Subjects were asked to describe how they thought they would act in various situations. Behavioral observations of actual disclosure patterns in dyads and triads would increase our confidence in these findings. We hypothesized that in a fairly unstructured leaderless discussion, conversations among dyads would be more intimate (i.e., contain greater depth of self-disclosure) than conversations among triads.[6]

[5] The results of this experiment were almost wholly replicated with a second larger sample ($n = 26$), using different items and role pairs. In the replication the predicted main effect of group size was again obtained ($p < .005$). A significant Group Size × Information interaction ($p < .05$), similar in interpretation to the one obtained in the first study, was also obtained.

[6] In Experiment 2 an instructional variable (discuss intimate vs. discuss nonintimate topics) could have been included to replicate the group size interaction effect in Experiment 1. Although such an instructional variable was considered, we decided against it because (a) such an instructional variable would make the conversations less natural and (b) we felt it was appropriate to replicate the group size main effect before seeking to replicate any interaction effects.

Method

Subjects and procedure. Freshmen in on-campus housing at Johns Hopkins University were solicited as volunteers by an experimenter. He explained that he was conducting a survey to find out how groups of freshmen felt about the quality of life on campus. The freshmen were randomly asked to contact either one or two of their acquaintances and arrange a time for a group discussion. The experimenter returned to the volunteer's room with a tape recorder at the time appointed for the discussion.

A total of 35 freshmen (19 males and 16 females) agreed to participate. Subjects were grouped into seven same-sex dyads (2 male and 5 female) and seven same-sex triads (2 female and 5 male). Each grouping was composed of acquaintances (i.e., friends the original contact had brought with him/her to the group discussion).[7]

When he arrived at the dorm room, the experimenter explained that the purpose of the discussions was to find out how groups of subjects felt about the quality of life on campus. Fully informed consent was obtained from the subjects.

The experimenter set the general outline for the discussions: "Talk about any problems concerning undergraduate life that you have encountered here as freshmen. Your discussion should, as much as possible, focus on sharing specific personal experiences that each of you has had related to the topic." After answering any further questions the experimenter started the tape recorder and left the room. He was not present during the discussions so that he would not disturb the natural atmosphere of the interactions.

After 9–12 minutes of conversation, the experimenter returned to the room and terminated the discussion. To compensate for increased resource input, triads were allowed a longer discussion time (M = 10.5 minutes) than dyads (M = 9.3 minutes). A short postdiscussion questionnaire was handed out to the subjects. The questionnaire assessed subjects' perceptions of various aspects of the group discussion, subjects' level of acquaintance with other group members, and subjects' general level of disclosure of their personal worries to other role figures (roommate, parents, best friend of the opposite sex, and best friend of the same sex). All questions used a 7-point rating scale, except for the question on level of acquaintance, which used a 4-point scale. Rate of disclosure across the four role pairs was summed to establish a general rate of disclosure of intimate information for each subject. After completing the questionnaire, subjects were fully debriefed.

Results and Discussion

The unit used in all analyses was the group mean. One-way analyses of variance were used to test the effects of group size on two sets of dependent variables: the intimacy of the group discussions and subjects' perceptions of the discussions.[8] The effects of group size were first assessed with no variables held as covariates and then with sex composition, mean level of acquaintance, and mean disclosure habits held as covariates.[9]

Intimacy of discussions was strongly influenced by group size, $F(1, 12) = 21.2$, $p < .001$ ($\hat{\omega}^2 = .59$). As predicted, the discussions of triads were less intimate than the discussions of dyads (see Table 2). The

---

[7] Some previous self-disclosure research has observed that females disclose more readily than males (cf. Cozby, 1973). Thus, one might argue that by overrepresenting females in the dyad condition we are biasing the sample in favor of our hypotheses. However, in this experiment sex composition was not correlated with any of the questionnaire or behavioral dependent variables (all ps $> .05$). This internal analysis indicates that although females were slightly overrepresented in the dyad condition, this did not actually influence the results.

[8] The conversations were transcribed. In the transcripts, there was no indication of the number of people in a particular group. Using a 4-point intimacy scale, each conversation was rated independently by one of the experimenters and by an individual who was totally unfamiliar with the experiment and its purposes. Interrater reliability was assessed using the intraclass correlation (Winer, 1962). Reliability between the two sets of ratings was .96. The mean ratings averaged across the two raters were used in the analysis. The estimated reliability of these mean ratings was .98.

The intimacy scale used was as follows: 1 = little or no disclosure (discussants shift focus away from selves), 2 = superficial or conventional disclosure (reveal trite or peripheral aspects of selves), 3 = personal disclosure (reveal specific experiences concerning more personal topics), 4 = intimate disclosure (specific experiences concerning more personal topics are discussed, and subjects clearly discuss their responses to these experiences).

[9] The analysis of covariance (ANCOVA) used here represents, in the terminology of Evans and Anastasio (1968), Usage 2 of ANCOVA: " 'Adjustment' of treatment means for differences between intact groups, when the covariate is unrelated to the treatments" (p. 227). The covariates used in this analysis (sex composition, level of acquaintance, and disclosure habits) were all statistically independent of the treatment (all rs $< .30$, all ps $> .10$). Furthermore, these covariates were statistically independent of questionnaire (amount learned) and behavioral (rated intimacy of conversations) treatment effects (all rs $< .40$, all ps $> .05$). These correlations are small. Evans and Anastasio note that "small correlations such as might occur . . . in the context of Usage 1 or 2, might not have serious consequences" (p. 233). Thus, in this analysis the usage of ANCOVA was appropriate and was not seriously biased by the small violations of the assumptions of independence.

Table 2
Behavioral and Perceived Effects of Group Size in Experiment 2

Condition	Dependent variable	
	Intimacy of discussion	Amount learned about others
Dyad	2.79	3.36
Triad	1.43	2.24

Note. Intimacy of discussion means were derived from ratings of the transcripts; a higher mean indicates a more intimate discussion. Amount learned means were obtained from subjects' answers to the question: "As a result solely of this discussion, how much do you think you have learned about the other people in the group?," with a higher mean indicating more learned.

influence of group size remained strongly significant with sex composition, acquaintance level, and disclosure habits held as covariates, $F(1, 9) = 12.0$, $p < .01$.

The covariate of acquaintance influenced the intimacy of the discussions, although the effect was much smaller than the effect of group size. Better acquainted groups had more intimate conversations, $F(1, 9) = 5.5$, $p < .05$.

On the postdiscussion questionnaires, the amount subjects learned about other group members was influenced by group size, $F(1, 12) = 5.4$, $p < .05$ ($\hat{\omega}^2 = .30$), with members of dyads learning more about others in the group than members of triads (see Table 2). This result is consistent with the finding that dyads had more intimate discussions than triads. The effect of group size on amount learned persisted, with the three covariates held constant, $F(1, 9) = 7.2$, $p < .05$. Furthermore, amount learned due to the discussion was solely a function of group size. (For all covariates, $Fs < 1$.) Amount learned due to the discussion was independent of other dimensions assessed by the questionnaire. The highest correlation between amount learned and other questions about the interaction was .32.

Members of dyads tended to perceive their discussions as less awkward and more intimate than did members of triads. These effects, although in the hypothesized direction, did not attain the accepted .05 level of statistical significance.

On the questionnaire results, there were two significant effects due to covariates. First, groups composed of members with high disclosure habits perceived the group discussions as less awkward, $F(1, 9) = 14.4$, $p < .01$. Second, the perceived intimacy of the topic discussed was influenced by the level of acquaintance of group members, with better acquainted groups perceiving their discussion topic as more intimate, $F(1, 9) = 14.0$, $p < .01$.

General Discussion

Two experiments using dissimilar methodologies have supported the hypothesis that individuals, when interacting with acquaintances, are more likely to disclose intimate information in a dyad than in a triad. These results support Derlega and Chaikin's (1977) suggestion that intimate disclosure depends on a closed dyadic boundary, that is, the revealer perceiving that his/her message is safe with the recipient. Disclosure was less intimate in triads in which the closed dyadic boundary did not exist. Furthermore, both experiments provided strong evidence that disclosing behavior closely corresponds to the perceived nontransitive nature of "confides in" (De Soto & Kuethe, 1959). Thus, sharing secrets is not only perceived as a pairwise interchange dividing people into dyads but, behaviorally, confiding actually appears to operate in this fashion. (See also Rubin & Shenker, 1978.)

Although there are other differences between dyads and triads in terms of role conflict (Brown, 1965), unanimity of mood (Heider, 1958), and coalition formation (Mills, 1953), the pattern of findings in Experiment 1 (see also Footnote 5) strongly supports our interpretation of the findings. With more intimate items of information and more intimate role pairs, the difference between disclosure rates in dyads and triads increased. Although the magnitude of these interaction effects was not large, the effects were congruent with prior research (Chelune, 1976; Spinner, Note 1). Furthermore, these interaction effects help clarify the role of the closed dyadic boundary. It appears that the salience of the boundary

increases as the confidentiality of the interchange increases.

In a public setting in which strangers are interacting and disclosure is likely to be nonintimate, our theoretical rationale would lead us to expect no effect of group size on disclosure. This was the result obtained by Rubin (1976) in his field experiment. Although it is hazardous to make inferences from negative findings, Rubin's failure to obtain a group size effect in a low disclosure setting is in line with the perspective presented here.

One limitation of the present study is that the effects of group size were explored only over a narrow range. However, this limited range of group sizes was a legitimate focus, since the differences between dyads and triads are more dramatic than the differences between other pairs of group sizes (cf. Hackman & Vidmar, 1970; O'Dell, 1968).

The results of the present study go some distance toward understanding the inherent quality of intimacy that Simmel (Wolff, 1950) attributes to dyads. However, the reasons for this quality are not as yet fully illuminated. Our expectation is that the intimacy of dyads is due to particular perceptual properties (e.g., perceived climate) and structural properties (e.g., role complexity and intensity) that covary with group size.

Furthermore, the present study highlights a host of questions that should be attended to by researchers in self-disclosure. What is the relationship between reciprocity and group size? Although reciprocal disclosure is straightforward in a dyad and involves only one input and one output channel, it is probably more complex in larger groups. In a triad each individual receives two sets of incoming messages and can send two different sets of messages, although everyone "overhears" everyone else's messages. In a triad, people may avoid the difficulties of maintaining two separate channels by disclosing at a uniform low level of intimacy. The apparent robustness of Jourard's dyadic effect and the reciprocity underlying it may in part be due to the past research focus on dyads.

Also, given that context factors such as group structure and central stimulus characteristics such as qualities of the target both influence disclosure patterns, what is the relative impact of each of these on disclosure? Consideration of this question should lead researchers to a more comprehensive understanding of the determinants of self-disclosure.

Expressive Tendencies and Physiological Response to Stress

Clifford I. Notarius
Catholic University of America

Robert W. Levenson
Indiana University

This study assessed the effects of natural expressive tendencies on physiological response to stress. Male undergraduates were unobtrusively observed while watching a stressor videotape. On the basis of the subjects' facial responsiveness to the film, a group of 23 natural expressers and 22 natural inhibitors were selected and exposed to a threat of shock situation during which heart rate, respiration rate, skin conductance, and facial expressions were monitored. In accord with the discharge model of emotion, natural inhibitors were less facially expressive and more physiologically reactive to the shock threat than were natural expressers. The results also demonstrated that overt expressivity is stable over time and situation. On personality measures, natural expressers scored significantly higher on Mehrabian's empathic tendency scale, thus supporting the efficacy of this paper-and-pencil instrument as a measure of nonverbal responsiveness. The two groups did not differ on measures of self-esteem, introversion–extraversion, or locus of control. The results are discussed in terms of the discharge model as a descriptive metaphor and not a causal theory.

Understanding the relationship between overt emotional expression and physiological response is necessary for a comprehensive theory of emotion as well as for an adequate conceptualization of behavior change following any of several expressive therapies (Nichols & Zax, 1977). Facial display is one component of emotional expression that has been shown to influence both physiological reaction patterns and the subjective experience of emotion (e.g., Izard, 1978; Laird, 1974). Although there is agreement that facial display is an important component of emotional response, there is conflicting evidence about whether facial display attenuates (Buck, Miller, & Caul, 1974; Buck, Savin, Miller, & Caul, 1972; Lanzetta & Kleck, 1970) or augments (Lanzetta, Cartwright-Smith, & Kleck, 1976) physiological response to emotionally arousing situations.

Lanzetta and Kleck (1970), Buck et al. (1972), and Buck et al. (1974) used an encoding/decoding paradigm to study the relationship between facial displays of emotion and physiological response to arousing situations. In these studies, a sender subject was exposed to an emotionally arousing event while an observer subject watched the subject's face on a video monitor and attempted to decode the sender's expression. The sender's skin conductance or heart rate or both were monitored throughout the stimulus presentation. The results of these studies indicated that the observer subjects were most accurate at decoding the facial expressions of sender subjects who were least physiologically reactive to the eliciting stimuli; conversely, observer subjects were least accurate at decoding the facial expressions of sender subjects who were most physiologically reactive. The results of these studies, which imply that reduced decoding accuracy was due to relatively fewer facial expressions, have been interpreted as support for

This article is based on data collected as part of the first author's doctoral dissertation.

the discharge model of emotion according to which facial expressions are associated with attenuated physiological response to emotional stimuli.

Unfortunately, the encoding/decoding paradigm does not provide a strong empirical test of the discharge model. In the studies that used this paradigm, the assessment of overt expressivity was dependent on the measure of decoding accuracy and the implication that this measure reflects overt expressivity. A more direct test of the relationship between facial expressiveness and physiological reactivity would be to place subjects in an arousing situation with trained raters recording the extent of their facial expressiveness. This methodology would enable an objective assessment of a subject's tendency to facially display a response to an emotionally arousing situation. Comparison of the objectively rated facial display data with recorded physiological response data would allow a test of the discharge model in situations in which natural response tendencies would most likely be evidenced.

An alternative approach is possible in which an attempt is made to directly manipulate the extent of facial responsiveness. Lanzetta et al. (1976) tested the discharge model in a well-designed study incorporating experimentally manipulated facial displays and independent assessment of expressivity during exposure to electric shock. Lanzetta et al. instructed subjects to either pose an intense expressive reaction or to pose no reaction to electric shock and found that subjects who were instructed to pose no reaction were significantly less *physiologically* reactive to the shock than subjects who had posed an intense reaction. These results are opposite to predictions based on the discharge model. Lanzetta et al. interpreted their results as support for proprioceptive feedback models of emotion (Gellhorn, 1964; Izard, 1971).

The discrepancy between Lanzetta et al.'s (1976) findings and previous support for the discharge model (Block, 1957; Buck et al., 1974; Buck et al., 1972; Jones, 1950; Lanzetta et al., 1970; Learmonth, Ackerly, & Kaplan, 1959) may stem from differences across studies in the operationalization of emotional expressivity. With the exception of Lanzetta et al.'s (1976) study, all previous investigations that found support for the discharge model allowed subjects access to their natural emotional responses during exposure to an eliciting situation. Thus, as Lanzetta et al. suggest, short-term, experimentally manipulated control of emotional expression may lead to a positive relationship between facial expression and physiological reactivity, whereas natural response patterns may be characterized by the discharge model.

One possible mediator of this short-term, positive relationship may be patterns of general somatic activity that are activated by instructions to "be responsive." To the extent that subjects become more physically active, one would expect such activity to be accompanied by increases in heart rate and skin conductance. Conversely, if instructions to hide responses produce a decline in somatic activity and a more general state of relaxation, decreases in cardiac and electrodermal activity might follow. In any event, it seems likely that results derived from experiments that involve natural expressive tendencies will differ from the results obtained from direct manipulation of expressivity, insofar as the two methodologies reveal different aspects of the relationship between facial expressivity and physiological responsiveness.

The purpose of the present study was to determine the relationship between facial displays of emotion and physiological reactivity to stress in subjects whose natural expressive styles were unconstrained. The experimental design incorporated a behavioral coding of facial expressivity (Mehrabian, 1972) and multiple measures of physiological reactivity (heart rate, respiration rate, and skin conductance). Based on the consistency of findings from studies in which subjects were allowed their natural emotional responses, it was predicted that natural expressers would be less physiologically reactive to an emotionally arousing situation than natural inhibitors.

A secondary purpose of the study was to explore personality correlates of expressive tendencies. Buck et al. (1974) reported that expressers were higher in self-esteem and were more extraverted than inhibitors. In the present study, subjects were assessed on self-esteem, introversion–extraversion, and empathic tendency.

Method

Subject Selection

To test the experimental hypotheses, it was necessary to preselect a group of natural inhibitors (persons who show little or no facial responsivity to an emotional situation) and a group of subjects who were natural expressers (people who show high levels of facial responsivity to an emotional situation). Seventy-six male undergraduates enrolled in introductory psychology classes were recruited for the preselection phase of the experiment; they were fulfilling a course requirement.

To establish natural expressive tendencies, subjects were shown an industrial accident film that had been demonstrated to be emotionally arousing (Lazarus, Opton, Nomikos & Rankin, 1965). The subjects were told that they would view a brief film and then be asked to complete several questionnaries. The questionnaires were Mehrabian's empathic tendency scale, Eysenck's Introversion–Extraversion Scale, Rotter's Locus of Control Scale, and Janis and Field's Self-Esteem Inventory.

Subjects viewed the industrial accident film in groups of four to six while three coders (two undergraduates and the first author) observed through a one-way mirror. Throughout the film, coders counted the number of facial expressions occurring in 30-sec time periods and entered this number on a coding sheet. Criteria for determining the occurrence of a facial expression were based on a procedure described by Mehrabian (1972). Using this procedure, changes from a neutral display to a nonneutral display and back to a neutral display constituted one facial expression. Gestural behaviors, such as slight movements of the eyebrows or touching the face with the hand, were not counted as facial expressions. Although more elaborate qualitative coding schemes exist for classifying facial displays in terms of discrete emotional states (Ekman & Friesen, 1975), it was decided to use a relatively simple quantitative coding system in this study to determine if a general relationship between natural facial expressiveness and physiological reactivity could be detected using a stress paradigm.

In addition to recording the number of facial expressions, coders assigned a subjective rating on a 10-point scale to each subject after the film, with 0 indicating little overt expressivity and 10 indicating a high level of expressivity. For all groups of four to six subjects, each coder observed three subjects, thus generating three independent codings of at least one subject during each screening of the film. This coding overlap permitted continuous reliability estimates throughout the subject selection procedure. Correlations between observers' codings averaged .88 (range, .79 to .95 for the number of expressions) and averaged .91 for the subjective index (range, .85 to .95).

Subjects who received a behavioral rating of 9 expressions or more and a subjective rating of 5 or more were classified as natural expressers, whereas subjects receiving a behavioral rating of 3 expressions or less and a subjective rating of 1 or less were classified as natural i-' ›rs. On this basis, 23 natural inhibitors and 22 natural expressers were selected for continuation in t experiment.

Procedure

A single laboratory appointment was arranged f each of the 45 subjects selected for continuation in t experiment. As each subject arrived at the laborator he was seated in a comfortable chair in front of a vid monitor and an unobtrusively placed video camera. T subject was told that he would be viewing a film on t monitor and that the experimenters were interested people's physiological reactions to the film. Physiolog cal sensing devices to detect heart rate, respiration rat and skin conductance were then attached to the subjec and he was told that the experimenter (one of two r search assistants blind to the experimental hypothese was going to set up the film and check to see that th physiological recording equipment was workin properly.

Just prior to leaving the subject, the experimente informed the subject that he would soon see a "digita voltmeter" displayed on the monitor via a close circuit TV camera placed in the adjoining room. Th subject was told that the "voltmeter" indicated th voltage flowing through his body as measured by a cli (actually a ground clip) attached to his ear. Th experimenter explained that the meter had an intern circuit to sense rapid increases in voltage and that if th internal circuit was activated, "9999" would begin t flash as a warning that a dangerously high level o voltage was present and that a strong shock coul result. The subject was then asked to monitor th voltmeter and to signal the experimenter immediatel if 9999 began to flash by ringing a buzzer conveniently placed to the subject's right. The experimenter asked if the subject had any questions and then left, tellin the subject that he had to check the recordin equipment.

In reality, the monitor displayed a videotape th was identical for all subjects and on which was record a small digital light display of four numbers. The pre programmed display presented "0000" for 4 min, lead ing to small increases over the next 30 sec until 999 began to flash on and off for 1 min. The flashing display of 9999 constituted the threat of shock. As soon as the subject signaled the onset of 9999, the experimente began to jiggle the wires in the adjoining room as if to attempt to locate the "problem." A loud thump on the wall was produced to accompany the return of 0000 to the video monitor; then 0000 remained on the monito for 4.5 min (the poststimulus period). The experimente entered the subject room and apologized for the flashing 9999 by explaining that this was the first time this had happened, that the cause was located and corrected, and that the subject was in no danger. The subject was then shown a second stressor film and exposed to an additional arousing situation before being debriefed.[1]

[1] Only data gathered in response to the threat of shock are reported. Although all subjects watched the film and were exposed to a third eliciting situation, it

Monitoring physiological responses. Skin conductance was measured by passing a constant voltage between two Beckman electrodes placed on the volar surfaces of the middle segments of two fingers of the right hand. Heart rate was recorded bipolarly using Beckman surface electrodes. Respiration rate was assessed by stretching a mercury strain gauge 10 inches (25.4 cm) in length above the subject's waist. Physiological signals were passed through a Grass Model 7 polygraph and routed through the analog-to-digital converter of a PDP-11 computer for on-line processing.

Monitoring facial expressivity. Facial expressivity was coded by the same coders using a similar procedure to that used in the preselection of subjects, with the exception that only one coder rated each subject.[2] The coder watched the subject's face on a closed-circuit video monitor located in a separate room and pressed a button for the duration of each nonneutral facial display. In the case of expressions maintained over 5 sec, the computer automatically counted an additional expression. Coders were blind as to which group the subject was assigned.

Videotape functions. The videotape served two functions, (a) to present the threat of shock stimulus to the subject and (b) to signal the end of the trial periods to the computer. An inaudible signal (17,000 kHz) placed on the videotape at spaced intervals (30 sec during stimulus presentations and 90 sec during baseline periods) momentarily closed a decoding switch, signaling the computer to begin a new trial period. The videotape continued for the duration of the experiment to ensure identical timing of the experiment for each subject.

Dependent measures. The computer was used to obtain the following dependent variables: (a) heart rate (interbeat interval)—time, in msec, between heart beats; (b) respiration rate (intercycle interval)—time, in msec, between inspiration and expiration cycles; (c) skin conductance—skin conductance, in micromhos; and (d) facial expression—the number of facial expressions coded.

Results and Discussion

Physiological reactivity was assessed by comparing average responses occurring in a 4.5-minute prestimulus period with average responses occurring in a 1-minute stimulus period. A 4.5-minute poststimulus period was compared with the prestimulus period to determine the extent of return to resting levels following exposure to an emotionally arousing situation. Dependent variables were entered into a Groups × Trials repeated measures analysis of variance with two groups (natural inhibitors and natural expressers) and three trials (prestimulus, stimulus, and poststimulus). Planned comparisons by t test were used to test specific reaction patterns of natural expressers and natural inhibitors.

Due to equipment malfunction, heart rate data were lost for one natural inhibitor across all stimulus periods, respiration rate data were lost for one natural expresser during the stimulus period, and skin conductance data were lost for one natural expresser across all stimulus periods and for one natural expresser during the prestimulus period. The remaining available data from these subjects were included in the analyses.

Stability of the inhibitor–expresser dimension. The preselection of subjects was intended to yield two groups of subjects who differed in the tendency to display facial expressions in response to emotionally arousing situations. In the absence of evidence concerning the stability of the tendency towards overt facial displays of emotion, it was hoped that a selection procedure based on behavioral observations of expressions in response to a stressor situation would be most likely to reliably identify the two groups. Examination of the mean number of facial expressions displayed in response to the threat of shock stimulus indicated that natural expressers averaged significantly more facial expressions than did natural inhibitors, $t(86) = 2.53$, $p < .025$; the mean numbers of expressions were 1.34 and .87, respectively. This result confirms the preselection classification of subjects and demonstrates stability of expressive tendencies across two independent situations (film and threat of shock) and across time (approximately 9 weeks separated the preselection film and the threat of shock situations).

Assessment of the arousing situation. Since the threat of shock was a novel stressor, it was important to determine whether subjects found the situation arousing. A significant trials effect

---

was decided that the within-subject design used in this study did not permit valid interpretation of the physiological data gathered following the threat of shock.

[2] Even though several months had passed since the preselection phase of the experiment, every attempt was made to ensure that a given subject's facial expressions were coded by a different rater in the preselection and laboratory phases of the research. Use of separate groups of coders in both phases of the study and having two coders per subject in the laboratory phase (to allow continuation of reliability monitoring) would be desirable in future work.

Table 1
Physiological Reactivity Patterns for Inhibitors and Expressers

Subjects	Measure	Prestimulus	Shock threat	Poststimulus
Inhibitors	Heart rate[a]	865	818*	882
	Respiration rate[b]	3648	3298*	3621
	Skin conductance (micromhos)	12.7	16.6*	15.7*
Expressers	Heart rate[a]	823	820	838
	Respiration rate[b]	3593	3530	3687
	Skin conductance (micromhos)	10.8	14.5*	12.9*

[a] Time in msec between heart beats.
[b] Time in msec between inspiration and expiration cycles.
* Significantly different from prestimulus level ($p < .001$).

was found on all dependent measures, indicating that the threat of shock was a physiologically arousing situation; for facial expression, $F(2, 86) = 35.12$, $p < .001$; for heart rate, $F(2, 84) = 11.21$, $p < .001$; for respiration rate, $F(2, 85) = 10.61$, $p < .001$; and for skin conductance, $F(2, 83) = 49.49$, $p < .001$. Anecdotal data gathered during the debriefing also indicated that the subjects found the situation arousing and believable. One subject, for example, related, "When the nines began to flash I really thought I was in for it."

Reactivity patterns in natural expressers and natural inhibitors. On measures of heart rate and respiration rate, natural expressers were less reactive to the threat of shock stimulus than were natural inhibitors. Natural inhibitors showed a significant heart rate increase, $t(84) = 3.76$, $p < .001$, and a significant respiration rate increase, $t(85) = 4.34$, $p < .001$, from the prestimulus to the stimulus period, whereas natural expressers showed no significant change from prestimulus levels in heart rate, $t(84) = .28$, *ns*, or respiration rate, $t(85) = .78$, *ns*. During the poststimulus period, heart rate and respiration rate of both groups returned to prestimulus levels. Heart rate and respiration rate means are presented in Table 1. These results are consistent with the discharge model.

Analysis of the skin conductance measure indicated that both groups were similarily reactive to the threat of shock; natural inhibitors showed a significant increase in skin conductance from prestimulus levels, $t(83) = 7.11$, $p < .001$, as did natural expressers, $t(83) = 6.67$, $p < .001$. During the poststimulus period, each group maintained a significantly higher skin conductance level relative to the prestimulus period, $t(83) = 5.49$, $p < .001$, for natural inhibitors; $t(83) = 3.89$, $p < .001$, for natural expressers. Skin conductance means are presented in Table 1. Skin conductance reactivity patterns did not discriminate natural expressers from natural inhibitors, as would be predicted on the basis of the discharge model.

Resting levels of natural inhibitors and natural expressers. Although reactivity patterns from the prestimulus to the stimulus period are the critical test of the discharge model, baseline differences occurring in the prestimulus period were also assessed. Natural expressers displayed a faster heart rate during the prestimulus period than did natural inhibitors, $t(84) = 3.35$, $p < .001$; whereas natural inhibitors displayed a significantly higher skin conductance level than did natural expressers, $t(83) = 3.49$, $p < .001$. The two groups did not display any prestimulus respiration rate differences, $t(85) = .68$, *ns*.

These baseline differences, observed in subjects who had just entered the laboratory and who were told only to monitor a "voltmeter," were unexpected. Furthermore, the pattern of the baseline differences indicated that one group was not simply more aroused to the general laboratory situation than the other group, since heart rate was elevated for natural expressers whereas skin conductance was elevated for natural inhibitors. These findings,

together with the lack of correspondence between skin conductance reactivity and heart rate and respiration rate reactivity, suggest that expressive tendencies may be associated with differences in individual physiological response stereotypy (Roessler & Engel, 1974) between expressers and inhibitors. This interpretation is offered tentatively, pending replication and extension of the results.

Personality correlates of expressive tendencies. Natural expressers were shown to be significantly more empathic on Mehrabian's empathic tendency questionnaire than were natural inhibitors, $F(1, 43) = 5.37$, $p < .025$. In a series of studies, Mehrabian (1972) presented evidence that overt responsiveness is the primary characteristic of subjects who score high on this questionnarie. Thus, the empathic tendency questionnaire appears to have discriminative validity.

The two groups did not significantly differ on measures of introversion–extraversion, self-esteem, or locus of control. These results are contrary to the findings of Buck et al. (1974).

Conclusion

The results of the present study are consistent with the discharge model; expressive subjects were significantly less physiologically reactive to an emotional stressor than were nonexpressive subjects. Furthermore, the stability of the inhibitor–expresser dimension over time and situation suggests an enduring attribute of affective style. However, it would be inappropriate, on the basis of these data, to conclude that facial expression functions as a causal agent in determining the parameters of physiological response to stress. More appropriate experimental designs for examining the causal relationship in which expressiveness is directly manipulated (e.g., Lanzetta et al., 1976) have produced results that are discrepant with the discharge model. This discrepancy between the results of studies in which subjects were allowed their natural response patterns and those in which subjects were asked to control their emotional expression underscores the fact that the discharge model is a descriptive metaphor for clinical and empirical findings that expressive individuals are less physiologically reactive to stress than are natural inhibitors. The fact that facial expressions are not mediating the relationship between expressivity and physiological reactivity leads to speculation concerning a third factor or factors that are responsible for the observed relationship.

Speculatively, the causal factors mediating the observed relationships between expressivity and physiological reactivity may involve the subject's cognitive appraisal of the eliciting situations. Given personality differences between expressive and inhibited subjects (Block, 1957; Jones, 1950; Learmonth et al., 1959), it would not be unexpected to find characteristic differences between the groups in the cognitive processes that function to shape an emotional response out of an environmental stressor. According to Lazarus, Averill, and Opton (1970), the outcome of these cognitive, subjective processes is an appraisal of the eliciting situation (along such dimensions as perceived danger, threat, or security) that determines a complex emotional response, which includes both overt expression and physiological response. Prestimulus differences in physiological levels observed in the present study may reflect the operation of differential appraisal from the moment the subjects entered the laboratory environment.

Attempts to refine our understanding of the determinants of different physiological reactivity patterns between expressive and nonexpressive individuals, whether or not cognitive appraisal is the primary mediator, must acknowledge the influence of several factors that have yet to be addressed. The first of these is the possible role of stimulus specificity. Although the facial responses in the present study were similar for the accident film and the threat of shock, it is conceivable that other stimuli might produce different patterns of facial and physiological response. In this respect, it would be important to examine stressors of a more interpersonal nature as well as situations in which positive affect is elicited. Second, continued research must recognize that natural expressive tendencies cannot be equated with instructionally manipulated displays of emotion. Short-term control of expression does not seem to be the equivalent of an expressive response from an individual's natural repertoire. Third, a more qualitative coding of facial ex-

pressiveness would be useful in determining whether the discharge model is uncritical as to the nature of facial display or whether such dimensions as appropriateness of affect, duration of display, or specific emotion displayed improve the predictive power of the model. Finally, further refinements in the scope of physiological response analysis may be important. Although it is generally agreed that monitoring one physiological system (e.g., skin conductance) is insufficient for adequately assessing physiological response, there is less consensus as to how data from multiple physiological systems should be handled in light of such factors as stimulus specificity and individual response stereotypy, which may strongly influence the nature of interrelationships among facial and physiological indices of expressivity.

The Cognition–Emotion Process in Achievement-Related Contexts

Bernard Weiner, Dan Russell, and David Lerman
University of California, Los Angeles

Two experiments were conducted to examine the linkages between cognitions and emotions. In the first investigation, subjects reported a "critical incident," in which they succeeded or failed an exam for a particular reason (e.g., help from others, lack of long-term effort). They then recounted three affects that were experienced. The data revealed prevalent affects linked with success and failure regardless of the attribution for the outcome. But many emotions were identified that are associated with specific attributions (e.g., luck-surprise; others-gratitude and others-anger). In addition, dimensions of causal attributions, such as locus, also influence recollected feeling states, particularly esteem-related emotions. Hence, it was proposed that in achievement-related contexts there are three sources of affect elicited by disparate cognitions. In the second experiment, it was demonstrated that individuals can use emotional cues to infer why a success or a failure has occurred. The proposed cognition–emotion and emotion–cognition couplings appear to be symmetrical.

The research reported in this article was guided by the simple presumption that a variety of cognitions, particularly causal attributions, influence emotional reactions in achievement-related contexts. This belief recently found suggestive support in an investigation conducted by Weiner, Russell, & Lerman (1978). The questions raised in Weiner et al. provide the foundation for the research reported here.

Weiner et al. compiled a dictionary list of approximately 250 potential affective reactions to success and failure in an academic context. The dominant causal attributions for achievement performance were also identified (Elig & Frieze, 1975; Frieze, 1976). Then a cause for success or failure was given within a brief story format, the success- or failure-related affects that had been identified were listed, and the subjects reported the intensity of the affective reactions that they thought would be experienced in this situation. Responses were made on simple rating scales. A typical story follows.

> Francis studied intensely for a test he took. It was very important for Francis to record a high score on this exam. Francis received an extremely high score on the test. Francis felt that he received this high score because he studied so intensely [his ability in this subject; he was lucky in which questions were selected; etc.]. How do you think Francis felt upon receiving this score? (Weiner et al., 1978, p. 70)

A number of provocative findings emerged from this investigation. First, there were a group of "outcome dependent – attribution independent" affects that were rated as vividly and equally experienced, regardless of the perceived attribution or the "why" of success. Examples of affects given success were pleasure, happiness, satisfaction, and goodness, whereas for failure the outcome dependent – attribution independent affects included uncheerfulness, displeasure, and being upset.

In addition, for both success and failure many affects were discriminably related to specific attributions. Table 1 shows a subset of the causal attributions for success and failure and a label that best describes their distinguishing linked emotion.

This research was supported by Grant MH25687-04 to Bernard Weiner from the National Institute of Mental Health.

Table 1
Attributions and Dominant Discriminating Affects for Success and Failure

Attribution	Success	Failure
Ability	Competence	Incompetence
	Confidence	—
Unstable effort	Activation	Guilt
	Augmentation	Shame
Stable effort	Relaxation	Guilt, shame
Personality	Self-enhancement	Resignation
Others	Gratitude	Aggression
Luck	Surprise	Surprise

Note. Table 1 based on Weiner, Russell, & Lerman (1978).

Table 1 reveals that for success, attributions to ability were thought to give rise to feelings of confidence and competence; unstable effort ascriptions produced heightened activation and high potency emotions (e.g., being uproarious and delirious), whereas stable effort attributions brought about relaxation; personality attributions resulted in self-enhancement (e.g., conceit and pride); attributions to others were associated with gratitude; and ascriptions to luck were linked with surprise. Given failure, ability attributions were perceived as giving rise to feelings of incompetence; effort ascriptions generated reports of shame and guilt; personality attributions were linked with resignation; ascriptions to others caused vindictiveness and aggression; and bad luck produced surprise.

Many of the findings summarized in Table 1 seem obvious—as is often the case, "the truth is not new." Yet there were also unexpected results and unanticipated revelations. For example, the data suggest that whether success is followed by activation or calmness depends on a discrimination between long- and short-term effort as the perceived cause of the outcome. Experiments by Lazarus (1966) also suggest that arousal (i.e., activation) is a product of a cognitive appraisal process. This position contrasts with the well-known contention of Schachter (1964) that the labeling of internal arousal precedes and defines one's emotional experience.

Table 1 reveals some interesting comparisons between emotional reactions to success and failure. If personal ability is the perceived cause, then, as might be anticipated when the outcomes are diametric, the reported experiences for success and failure are in direct opposition: respectively, competence in contrast to incompetence. This antithesis is also evident when attributions are to others (the generated emotions for success and failure, respectively, are gratitude vs. hostility). But if luck is the causal attribution, then the reactions to both success and failure include surprise. And, given effort ascriptions, the feelings associated with success and failure—high activation or calmness versus shame and guilt—are unrelated.

In spite of the systematic and significant findings reported by Weiner et al. (1978), there is reason to be skeptical about the data. These investigators cautioned that

> This procedure is fraught with danger, even as a starting point. First of all, we assumed that individuals would project their own emotional experiences, or those observed in others, upon the characters in the stories. Second, we assumed that our labels reflect the "real" experiences of the subjects. Finally, we assumed that repression and surpression, memory distortion, response sets, experimenter demands, and individual differences in affective labeling as well as in the subjective meaning of these labels would not render our results meaningless (see Davitz, 1969). In sum, there obviously are many limitations of this initial study. (Weiner et al., 1978, p. 70)

Later it was warned that

> The reactive and respondent measure undoubtedly encourages subjects to report affects that are not experienced, or are experienced in a manner not truly captured by the labels. (Weiner et al., 1978, p. 71)

A series of follow-up studies was therefore initiated with the purpose of replicating the prior findings with altered methodologies and extending the research in new directions. The two investigations reported here introduce the changes given below.

(a) In Experiment 1, a "critical incident" technique (Davitz, 1969) is used in which subjects relate a personal experience of success or failure, given a designated causal attribution. Free responses, rather than rating scales of specific affects, are the dependent indicators of emotions. Thus, the procedure uses operant methods of affective assessment, whereas Weiner et al. (1978) used a respondent methodology (McClelland, 1971). In addition, the methodology is not simulational (although it is retrospective).

Table 2
Percentage of Subjects Recounting a Critical Incident as a Function of Outcome and Causal Attribution

Outcome	Attribution					
	Ability	Unstable effort	Stable effort	Personality	Others	Luck
Success	94	87	68	54	75	66
Failure	73	81	33	42	56	56

(b) In Experiment 2, affects are used as the independent variables to examine whether they can be used as information to infer thought processes (causal attributions).

In both experiments, a major empirical and theoretical goal is to determine whether the emotions linked with internal causal ascriptions cluster together and differ from the emotions associated with external ascriptions. In prior writings (e.g., Weiner et al., 1971) it was contended that the dimension of locus of causality (internal vs. external) mediates between success and failure and the emotional reactions to these outcomes, with affects heightened given feelings of internal responsibility. Weiner et al. (1978) isolated two sources of emotion—outcome and causal attributions—but failed to identify the role of locus of causality as a third determinant of affect (see review in Weiner, 1977).

Experiment 1

Method

The subjects were 79 male and female college students enrolled in introductory psychology at the University of California, Los Angeles, and participating to satisfy a course requirement. They were tested in groups ranging in size from 5 to 16.

Each subject completed a questionnaire in which 12 achievement conditions were represented. Each condition consisted of an outcome (doing well or poorly on a test) determined by one of six causes (ability, unstable effort, stable effort, personality, other people, and luck). These causes were selected because they showed the clearest relationships to different qualities of emotional experience in the Weiner et al. (1978) investigation. The subjects were asked, for example, to

> Think of a time when you did well on a test in a school subject that was very important to you. You felt that the reason you did well was that the teacher (or other people, such as friends) helped you a great deal.

The order of the 12 conditions (two outomes × six causes) was randomly varied between subjects.

The subjects were asked to try to recall a time when they had been in such a situation. If they could recall this type of personal experience, then they were asked for a brief description, including details such as the academic course, when the event occurred, and so on. It was hoped that this prompting would enhance the salience of the event. Finally, the subjects were asked how they felt in the situation, using three affective labels to characterize their emotional reactions. Short spaces for three words were provided on the questionnaire.

Research has indicated that subjects often do not have words readily available to describe their experiences. As an aid to subjects in characterizing and communicating their affective reactions, examples of six affects known from the Weiner et al. (1978) study to be associated with success (calmness, competence, conceit, exhilaration, gratitude, and pride), six affects known to be associated with failure (depression, fear, guilt, incompetence, resignation, and vindictiveness), and one associated with both success and failure (surprise) were included with the instructions. These were listed as "words that describe different types of emotion." Thus, the procedure was a mixture of free and guided recounting of emotional experience.

Subjects worked through the experimental conditions at their own pace. When the questionnaire was completed by all the subjects in a group, the experiment was discussed openly.

Results and Discussion

For all the reported analyses, no differences were found between the sexes; the data are collapsed across this variable. Table 2 shows the percentage of subjects recalling a critical incident in each of the 12 experimental conditions. Subjects reported more success experiences than failure experiences and outcomes associated with ability and effort attributions were also more likely to be recollected. An analysis of variance of these dichotomous data (see Winer, 1971, pp. 303–305) revealed a main effect of outcome,

Table 3
Percentage of Emotional Recollection as a Function of the Causal Attribution for Success

Affect	Ability	Unstable effort	Stable effort	Personality	Others	Luck
Competence	30*	12	20	19	5	2
Confidence	20	19	18	19	14	4
Contentment	4	4	12*	0	7	2
Excitement	3	9	8	11	16*	6
Gratitude	9	1	4	8	43*	14
Guilt	1	3	0	3	2	18*
Happiness	44	43	43	38	46	48
Pride	39*	28	39	43*	21	8
Relief	4	28*	16	11	13	26*
Satisfaction	19	24*	16	14	9	0
Surprise	7	16	4	14	4	52*
Thankfulness	0	1	0	0	18*	4

* $p < .01$.

$F(1, 858 = 39.39, p < .01$, attribution, $F(5, 858) = 21.44, p < .01$, and a significant Outcome × Attribution interaction, $F(5, 858) = 2.34, p < .05$. Within the given attributions, there was a greater likelihood of reporting success than failure in the ability, stable effort, and others conditions (for all conditions, $p < .01$).

The reported differences could indicate the operation of hedonic or defensive biases in attribution or memory or both. However, in the academic lives of these students, the data reported in Table 2 could readily be interpreted as reflecting the frequency of their actual experiences.

Success. The data analyzed for both success and failure outcomes are the percentage of subjects (based on those recounting a critical incident) who reported a specific emotional experience in response to the various achievement conditions. Only emotions listed by more than 10% of the subjects in response to any one of the causal attributions are included in the final analysis.

The 79 subjects listed 156 different emotions in response to the six success attributions. Of these emotions, 12 met the criterion of being given by more than 10% of the subjects for any given attribution. (See Table 3.) Four of these 12 emotions (competence, gratitude, pride, and surprise) were among the examples of emotions provided to the subjects; there was probably lability or influence on which labels subjects were willing to give to their experiences; perhaps a different set of exemplar affects would have yielded other specific emotional reports.

The most commonly reported affect, happiness, appeared in each condition with relatively equal frequency ($M = 44\%$). This response pattern depicts what we have labeled an outcome dependent – attribution independent emotion and, again, suggests that one source of achievement-related affect is linked with the perception of success and failure regardless of the reason for the outcome. Happiness was also one of the general reactions to success reported by Weiner et al. (1978); as in that investigation, the outcome-linked affect was notably dominant in the

Table 4
Discriminating Affects as a Function of Outcome and Causal Attribution

Attribution	Success	Failure

* $p < .01$.

present study. Confidence also was not discriminably linked with any particular affect, although confidence was not a reported affect, given the attribution of luck.

Table 4 lists the discriminating affects for each causal attribution. A discriminating affect is defined as one that is reported significantly more ($p < .01$) for one attribution relative to a composite of the other attributions. All comparisons were done using arc sine transformations, following the procedure suggested by Langer and Abelson (1972).[1] The linkages corresponding to those reported by Weiner et al. (1978; see Table 1) are ability-competence and ability-pride; stable effort – contentment;[2] personality-pride; others-gratitude; and luck-surprise. In addition, there were some associations that did not appear in the prior research: unstable effort – relief and satisfaction (rather than activation); others-excitment; luck-guilt and luck-relief. It is of interest to note that one of the reactions to success caused by luck is a negative affect.

Failure. In response to the six failure situations, 166 different emotional reactions were listed. Fifteen of these emotions were given by more than 10% of the subjects in response to at least one of the causal attributions (see Table 5). Six of these emotions (depression, fear, guilt, incompetence, resignation, and surprise) were included among the examples that were provided for the subjects and, again, apparently indicate their readiness to appropriate given labels. Of these 15 emotions, six (depression, $M = 23\%$; frustration, $M = 16\%$; disappointment, $M = 15\%$; upset, $M = 8\%$; disgust, $M = 5\%$; and mad, $M = 5\%$) were not discriminably associated with any single attribution. Weiner et al. (1978) also reported that frustration and upset were directly linked with failure outcomes. In the present data, three of these affects (depression, frustration, and upset) were reported to be significantly less experienced in response to a particular attribution—others, stable effort, and personality, respectively.

Table 4 also includes the discriminating affects for each of the causal attributions given failure. These discriminating affects

[1] For example, 30% of the subjects reported the emotion of "competent" given an ability attribution for success. In response to the five other attributions, 11% of the subjects reported competent as one of their three affects. Arc sine transformations were performed on these percentage figures and the difference between the arc sines was evaluated relative to an error term based on the number of subjects representing each percentage figure (Langer & Abelson, 1972).

[2] Although stable effort attributions yield the emotion of pride to as great an extent as do ability attributions, the linkage is not significant because the percentage is based on a smaller n.

Table 6
Dimension-Linked Affects as a Function of Outcome and Locus

Present study	Weiner et al.[a]	Present study	Weiner et al.[a]
Success—internal attribution		Success—external attribution

[b] Includes 19 affects related to anger (e.g., hostile, infuriated).
[c] Includes 5 affects related to surprise (e.g., astonished, startled).
[d] Seventeen unclassifiable affects (e.g., concerned, alarmed, hysterical).

were determined using the same procedure as for the success condition. The parallel linkages with those reported by Weiner et al. (1978; see Table 1) are ability-incompetence; stable effort – guilt; others-anger; and luck-surprise. The bonds between ability-resignation and ability-unhappiness, and between luck-sad and luck-stupid, were not exhibited in the prior research. However, there was previous evidence in support of the unstable effort – fear association.

Summary. The finding that certain emotions such as happiness and disappointment are independent of attributions but dependent on outcomes corroborates the results reported by Weiner et al. (1978). In addition, of the 12 attribution conditions, the stated emotions in 9 clearly replicate the prior findings. Perhaps what are least clear are the emotional labels given success or failure attributed to the presence or absence of a short-term burst of effort. In addition, in the present study the attribution of failure to personal shortcomings had no discriminably linked affects. But ascriptions of success or failure to ability, stable effort, others, and luck have idiosyncratic affective associates (see Table 4).

Causal dimensions. Further analyses were conducted to discover the relation between causal dimensions and affective responses. The emotional reactions to the four internal causes used in the present study (ability, unstable effort, stable effort, and personality) were compared with the reactions given the two external attributions (other people and luck). That is, the percentage figures from the four internal attributions were averaged and compared with the average of the emotional responses to the two external attributions, using arc sine transformations of the data. Table 6 shows that for success, pride, competence, confidence, and satisfaction, all were more likely to be experienced given internal rather than external attributions. On the other hand, external attributions were more linked with gratitude, thankfulness, surprise, and guilt than were internal ascriptions. (For all conditions, $p < .01$.)

The findings reported above are suspect because only a subset of the possible internal and external attributions were included among the experimental conditions. In Weiner et al. (1978), 10 causal attributions were examined (the present 6 plus mood, intrinsic motivation, task difficulty, and motivation and personality of others). These 10 account for the majority of attributions in achievement-related contexts (Frieze, 1976) and thus permit a better test of whether affects are tied to locus of causality. Reanalyses of the

Weiner et al. data, not previously reported, show a remarkably close correspondence with the present results (see Table 6).

In sum, the affects for success that are most intimately related to personal esteem (competence, confidence, and pride) are reported to be associated with internal attributions. On the other hand, external attributions are linked with affects, such as gratitude and thankfulness, that require an outside causal agent.

Table 6 also shows the dimension-related responses to failure. Again, there are clear correspondences between the two research studies. Internal attributions exacerbate feelings of guilt and what might be considered a giving up of the goal (resigned and aimless), whereas external ascriptions magnify anger and surprise. Guilt, therefore, emerges as an affective reaction for both success and failure, but given external attributions for success and internal ascriptions for failure. These data reaffirm the intertwining of achievement and moral motivational systems (see Weiner & Peter, 1973).

General Discussion

The data from the present study and the Weiner et al. (1978) investigation are sufficiently similar to warrant speculation about the emotional process in achievement-related contexts. We contend that emotions are a product of three distinct cognitive phases. Prior to elaborating this idea, however, it is important that the reader understand that we are going "beyond the data given." First of all, we have no immediate evidence concerning what people actually experience subsequent to success and failure. The experimental paradigm used by Weiner et al. (1978) might be called a simulated other-perception ("How do you think the person would feel?"), whereas in the present investigation the dependent variable is *recollected* emotions. We also cannot definitively state that emotions follow cognitions, because causal attributions for achievement events were not manipulated. In addition, it is possible that the reported cognition–emotion linkages are due to scripts—in this case, rules that guide which emotions should go with which cognitions, although individuals actually do not progress through cognition–emotion phases. A related approach to the data is that we are studying naive theories of emotion, or what a person thinks are appropriate cognition–emotion bonds.

The lack of methodological sophistication in the field of emotion and the limitations of our studies do not allow us to dispel with certainty these alternative interpretations of the data. Nonetheless, there is an account that we find most compelling for the time being. It is suggested that on experiencing an achievement-related outcome, actors first appraise their performance, assigning it a value on a continuum ranging from subjective success to subjective failure. This evaluation is likely to be based on some internal standard and aspiration level, consensus information, and so on. The success–failure judgment produces a positive or negative feeling of a certain intensity. The intensity no doubt is a function of many factors, such as the importance of the outcome, ego involvement, and long-term implications. The positive or negative reactions to success or failure are given labels, such as *happy* or *disappointed*. This emotional response may be the most short-lived and intense of the affective experiences in achievement contexts.

The actor then immediately and automatically or later and reflectively assigns a reason for the outcome. This could be an impulsive statement ("Was I lucky!") or a more reasoned judgment ("I believe I could not have succeeded without the help I received."). As a consequence of this ascription, a number of attribution-specific emotions follow, such as surprise or gratitude. Of course, there may be multiple perceived causality, in which case a number of distinctive emotions should be elicited.

Finally, the attribution(s) for success and failure is classified into causal dimensions, such as locus of causality. Further affective experiences then follow as a consequence of the fact that some of the ascriptions have implications for how one views oneself. Other attributional dimensions, such as stability, also appear to have affective implications (hopelessness vs. optimism; see Weiner et al., 1978; Weiner, 1979). We suspect that these dimension-tied affects have greater longev-

Table 7
Mean Magnitude of Attributional Inference Elicited in Response to the Indicated Emotional Description

Attribution inference elicited	Success—emotional description					
	confident competent pleased (ability)	uproarious delighted good (unstable effort)	calm relaxed secure (stable effort)	hopeful composed safe (task ease)	surprised astonished thankful (luck)	appreciative grateful modest (others)
Ability	8.06	6.25	6.21	6.10	3.10	4.56
Unstable effort	7.08	6.48	7.04	6.12	3.60	5.60
Stable effort	7.02	6.42	6.77	6.73	3.12	5.08
Task ease	4.67	5.75	5.25	5.08	4.65	5.54
Luck	2.60	2.73	4.73	3.94	7.31	6.08
Others	3.54	3.60	4.92	5.02	5.42	6.69

ity than the outcome- or attribution-linked emotions.

In achievement-related contexts, therefore, the actor might progress through various cognition–emotion scenarios, such as (a) "I just received a D on the exam. That is a very low grade." (This generates intense but relatively fleeting feelings of being frustrated and upset.) "I received this grade because I did not try sufficiently hard." (This is followed by feelings of guilt.) "There really is something lacking in me." (This is ensued by low self-esteem or lack of worth.) "What I lack I probably always will lack." (This produces hopelessness.)

Alternatively, there is (b) "I just received an A on the exam. That is a very high grade." (This generates happiness.) "I received this grade because I worked very hard during the entire school year." (This produces contentment and relaxation.) "I really do have some positive qualities that will persist in the future." (This is followed by high self-esteem, feelings of self-worth, and optimism.)

Experiment 2

Since emotions are coupled with cognitions, an emotional expression can act as a cue to an observer, allowing an inference about the cognitions of the actor. Hence, publicly masking our emotions often serves the function of hiding our thoughts, just as public emotional expression reveals our thoughts. In Experiment 2, we examined whether knowledge about an actor's emotions (here conveyed with verbal labels) enables an observer to infer an actor's causal attributions for an achievement performance.

Method

Six attributions used by Weiner et al. (1978) provided the foundation for the present investigation: ability, unstable effort, stable effort, task difficulty, others, and luck. Task difficulty, therefore, has replaced personality among the causal ascriptions varied in Experiment 1.

Two criteria were used to select the relevant affects associated with each attribution. Highly discriminating affects not intensely experienced might be so subordinate among the affects being expressed that they could not have a cue function. On the other hand, emotions strongly felt (and expressed) for all attributions cannot possibly have signal value for any one ascription. Hence, selection of the affects for each attribution was based on two criteria: the discriminating value of the affect multiplied by its absolute intensity rating (data from Weiner et al., 1978). Three emotions were selected for each of the six attributions; the affects chosen for this study had the highest values using this procedure. (See Tables 7 and 8.)

The subjects were 48 male and female students at the University of California, Los Angeles, participating as part of a course requirement. Twelve scenarios (two levels of outcome × six emotional descriptions) were randomly presented to each subject. A typical story scenario follows.

> A person just received a test back in a course that is very important to him or her. He or she has done very well and feels extremely *surprised*, *astonished*, and *thankful*. Why did this person believe that he or she did so well?

Table 8
Mean Magnitude of Attribution Inference Elicited in Response to the Indicated Emotional Description

	Failure—emotional description					
Attribution inference elicited	incompetent inadequate panicked (ability)	sorry ashamed scared (unstable effort)	humble guilty troubled (stable effort)	stunned sad displeased (task difficulty)	astonished overwhelmed surprised (luck)	bitter furious revengeful (others)
Ability	7.40	5.50	4.56	4.08	3.44	3.35
Unstable effort	4.92	7.48	7.40	3.54	2.73	3.67
Stable effort	5.46	7.56	7.81	3.94	2.90	3.81
Task difficulty	6.35	4.56	4.94	5.56	4.94	6.70
Luck	3.25	3.10	2.85	4.96	6.52	4.85
Others	3.48	3.60	3.58	4.79	3.85	6.75

This was followed by six scales anchored at the extremes with "definitely" and "definitely not," on which the judgments for the six causal ascriptions were made. The scales were divided into nine equal intervals and were randomized both within and between subjects.

Results and Discussion

Tables 7 and 8 show the mean ratings for each emotional description on the six attribution scales in the success and failure conditions, respectively. Inspection of the columns of the tables indicates the extent to which a particular emotional description is associated with the attributional judgments. If the emotion–cognition linkages and the cognition–emotion linkages are symmetrical, then the diagonals in the tables should contain the highest ratings within the columns. For example, the emotions known to be elicited by luck attributions (surprised, astonished, and thankful) should, in turn, lead to an inference of luck as the causal determinant. In the fifth column of Tables 7 and 8, the fifth row should (and does) contain the highest rating. In 9 of the 12 comparisons ($p < .01$) the a priori designated attribution is most highly rated, whereas in two other instances (stable effort emotions for success and unstable effort emotions for failure) the ratings are second highest. The one disconfirmatory finding involves task attributions for success, which primarily elicit the inference that stable effort was the cause of the positive outcome. However, the data in the Weiner et al. (1978) investigation were not very systematic for task attributions; for that reason, the task ascription was excluded from Experiment 1.

Statistical comparisons were performed contrasting the a priori "correct" attributional inference (that is, the attribution that was found to be associated with the emotional description in the Weiner et al., 1978, investigation) to the inferences given the five other attributions. Significant differences ($p < .01$) in the expected direction were found for all the emotional descriptions, except in the case of the emotions associated with task ease.

Causal Dimensions

Three of the attributions used in this study are classified as internal in locus of causality (ability, unstable effort, and stable effort) and three are external (task difficulty, luck, and others). The strength with which internal versus external causal attributions were inferred for each emotional description was then analyzed. In 11 of 12 comparisons, emotional descriptions associated with a particular internal attribution according to Weiner et al. (1978) elicited internal causal inferences significantly more than external causes, with the opposite being true of emotional descriptions associated with external attributions. (For all conditions, $p < .01$.) For example, the emotional description of confident, competent, and pleased, which was predicted to elicit ability

attributions, elicited ability, unstable effort, and stable effort, which are the internal attributions, to a greater extent than inferences that the external attributions of task ease, luck, and others were responsible for success. The lone exception to this pattern was again the emotional description associated with task explanations for success, in which internal attributions were more strongly inferred than external attributions. These data indicate that there is not only a strong inference of the a priori "correct" attribution given an emotional description, but one also infers attributions similar in locus of causality.

These data may not seem so surprising considering that two of the internal causal ascriptions involve effort. However, the external attributions are disparate and the emotional descriptions are extremely varied. There is an intimation that observers might engage in a two-step inference process, in which first the emotions are linked to a particular causal dimension and then there is a search for the particular cause. But at present it is not known whether specific causal judgments follow or precede dimensional placement or whether there is no systematic judgment sequence.

Instrumentality Effects in the Assessment of Racial Differences in Self-Esteem

Bernadette Gray-Little and Mark I. Appelbaum
University of North Carolina at Chapel Hill

Previous studies of racial differences in self-esteem have led to highly disparate and confusing results. This study shows that the effects of the measuring instrument as well as those of preexisting individual differences in academic and demographic characteristics are very great. These effects may be sufficient, in many cases, to explain the disparate results of earlier studies.

Attempts to measure racial differences in self-esteem, the evaluative component of the self-concept, have probably been more numerous than social comparisons of any other psychological variables except intelligence and school performance. Much of this research has proceeded on the hypothesis that blacks have degraded self-images and make reduced self-evaluations compared to whites. In many instances, this assumption is explicitly anchored in the self-theory of James (1890) or Mead (1934), both of whom linked self-concept to the evaluative feedback that one receives from important others in the social environment. Although there is substantial empirical support for the relationship between self-evaluations and appraisals from others (Wylie, 1968), such a relationship cannot be offered as conclusive proof of lower self-esteem in blacks. To assume that blacks have low self-esteem, it is also necessary to assume that an individual's self-concept is heavily dependent on society's evaluation of the group with which a person is identified (Cartwright, 1950; McCandless, 1970). Accordingly, since blacks as a group are less positively evaluated than whites, black individuals will have lower self-esteem than whites. There has been some support for this conclusion (Bridgette, 1970; Long & Henderson, 1968), but just as often no support (Gibby and Gabler, 1969; Rosenberg, 1965) or directly opposing results (Baughman & Dahlstrom, 1968; McDonald & Gynther, 1965; Powell, 1973; Rosenberg & Simmons, 1971; Wendland, 1969).

There are probably many reasons for the contradictory findings in this area of research. First, the assumption of correlation between one's self-esteem and society's evaluation of one's racial or ethnic group, although compelling in terms of common sense, has little empirical support. Rosenberg (1965) called this proposition the stratification hypothesis and found no relationship ($r = .04$) between an ethnic group's average self-esteem score and independent ratings of that group's status in society.

Second, the study of self-esteem has been plagued by a number of problems that make racial comparisons even more difficult. For example, self-esteem has been defined and measured in different and, at times, noncomparable ways (Wylie, 1968). Furthermore, subject characteristics such as sex, age, and grade have typically varied from one study to the next, with little attention paid to the relevance of these factors to racial differences found (Christmas, 1973). Moreover, in many instances important mediating factors, such as socioeconomic status and educational achievement, which are probably relevant to

This research was partially supported by grants to the first author from the University Research Council of the University of North Carolina and the Social Science Research Council's Committee on Grants for Research on Racism and other social factors in mental health.

self-concept and which are certainly pertinent to discussions of racial differences, have been neither controlled nor covaried.

The problems attendant on the confounding of socioeconomic status with racial/ethnic membership are illustrated in studies by Long and Henderson (1968) and Soares and Soares (1969). Long and Henderson found economically disadvantaged school beginners in a Southern community to have lower self-esteem scores than more advantaged children on the Self-Social Constructs Test. Soares and Soares asked fourth-grade through eight-grade children to rate themselves on a set of 20 bipolar trait descriptors and found that disadvantaged children had higher self-esteem scores than advantaged children. In the Long and Henderson study, all of the disadvantaged children were black and all of the advantaged children were white. In the Soares and Soares study, $\frac{2}{3}$ of the disadvantaged children were black or Puerto Rican whereas 90% of the advantaged children were white. Neither study made clear whether socioeconomic or racial factors account for the differences in self-esteem scores. Studies that have looked at the relationship between self-esteem and academic achievement have been somewhat more consistent in showing a positive relationship between educational achievement and self-concept scores (Freyberg & Shapiro, 1966; Caplin, 1969). There have, however, been investigations that revealed no differences in the self-concept scores of high-achieving and low-achieving students (Curtis, 1967; Lourenso, Greenberg, & Davidson, 1965).

Two studies that are particularly relevant to the present one and that highlighted the problems encountered in racial comparisons of self-esteem were those of Wendland (1969) and Bridgette (1970). These studies involved children in the same geographical area and, in some instances, in the same school system. Wendland found blacks to have higher self-esteem scores, whereas Bridgette reported higher self-esteem scores for whites. One obvious difference between the studies was that Wendland's subjects were attending segregated schools whereas Bridgette's subjects were in a recently desegregated school in which whites (who were the majority) had vigorously opposed integration. Another potentially relevant difference was the grade level and hence the age of the subjects tested—sixth-grade students in Wendland's study and eleventh-grade students in Bridgette's research. Since there may be different age trends in self-esteem for blacks and whites, it is unclear whether or not the contradictory findings were related to age. Perhaps most important, however, two different measures of self-esteem were used—Fitt's Tennessee Self-Concept Scale (TSCS) in Wendland's research and Coopersmith's Self-Esteem Inventory (SEI) in Bridgette's work. One might reasonably have expected the same results from these two instruments, since they purport to measure the same aspect of self-concept—self-esteem. Coopersmith (1967) described the SEI as a measure of "the evaluation an individual makes and customarily maintains with regard to himself . . . a personal judgment of worthiness" (p. 4). Similarly, Fitts (1965) characterized those who receive high scores on the Total Positive Scale, the most important subscale of the TSCS, as "persons who tend to like themselves, feel they are persons of value and worth" (p. 2).

There are, then, several factors, both theoretical and methodological, that might be important in explaining why some studies have shown blacks to have higher self-esteem scores than whites, whereas others have found whites to have higher scores. Among the methodological issues, one should consider the possibility that seeming racial differences may be attributable to differences in the socioeconomic status or academic achievement of the groups tested or to differences in the racial make-up, segregated or desegregated, of the school. Racial differences may also be artifactual.

The primary purpose of this study is to examine the extent to which the discrepant findings with regard to race are due to the instruments used to measure self-esteem. First, we focus on the race effects obtained on two instruments—the SEI and the TSCS—for junior high and high school students. Then, we examine the correlations of each instrument with important intervening socioeconomic and academic variables and observe whether the pattern of racial differences found with these

measures persists when the correlated variables are covaried.

There were several reasons for selecting these instruments. Both are widely used to measure self-esteem in school-age children. Both are intended to measure the evaluative component of self-concept and both are rating scales. Norms and reliability data are available for both instruments. Finally, because we had access to subjects from the same school systems used by Bridgette (1970) and Wendland (1969) in their investigations, we wished to use the same measures to enhance comparability with their data.

Method

The school system in Central North Carolina, from which our 735 subjects were drawn, is now desegregated. Small farms and textile mills are among the major employers in this area; most of the children live in a small town and its surrounding rural area. Our sample was composed of 146 black males, 145 black females, 238 white males, and 206 white females, with seventh-grade students accounting for roughly 54% of the sample, and the remainder being tenth-graders. The mean age of the seventh-grade students was 12.31 (SD = .68) and of the tenth-grade students, 15.33 (SD = .61). Half of the students at each grade level were tested with the SEI and the other half with the TSCS, yielding 372 SEI scores and 363 TSCS scores. Two female examiners, one black and one white, administered the tests to classroom groups. IQ (Form L of the Otis-Lennon Intelligence Test) and achievement scores (grade-appropriate forms of the Iowa Test of Basic Skills), as well as information regarding the number of children in the family and parents' educational and occupational levels, were obtained from the school records of the tested students. The achievement tests had been administered the previous semester. IQ scores were typically not more than 1 year old. Hollingshead's Two-Factor Index of Social Position (Note 1) was used to classify subjects' socioeconomic status.[1] A score of 1 indicates the highest social class; 5 indicates the lowest.

Two years after the initial testing with the self-esteem instruments, the original seventh-grade students were retested as ninth graders. The purpose of this testing was to allow us to examine changes in self-esteem over time as a function of race and sex and to compare the stability of the SEI scores with those of the TSCS scores. Of the 256 students that were available at the time of the follow-up, 128 had originally been tested with the SEI and 128 with the TSCS. A comparison of each of the two follow-up groups with the total group of subjects who had taken the same test showed them to be very similar. The follow-up SEI group had an average seventh-grade score of 65.44, whereas the total seventh-grade group had an average score of 64.99. Similarly, the follow-up TSCS group had an average seventh-grade score of 329.79, whereas the total seventh-grade group had an average TSCS score of 329.19. The scores for the original and follow-up samples tested with the TSCS are very similar to those found for junior and senior high school students in several other studies (For a review, see Thompson, 1972). The scores obtained by the SEI standardization sample (Coopersmith, 1967) were slightly higher than those obtained by our original and follow-up groups tested with the SEI.

Table 1
Analyses of Variance for Age, Race, and Sex Differences in Self-concept

Variable	SEI[a] (1, 364)	TSCS[b] (1, 355)
Age (A)	1.79	3.68*
Race (B)	11.81**	1.10
Sex (C)	.64	.40
A × B	.23	.54
A × C	.16	.01
B × C	.17	2.33
A × B × C	.02	.28

Note. Tests are those of effects eliminating other effects at the same level (e.g., age eliminating race and sex). See Appelbaum and Cramer (1974). Numbers in parentheses are degrees of freedom.

** $p < .001$.

Results

In the following section, we present analyses of the SEI and TSCS in terms of race and age differences as well as the relation of these tests to demographic and academic variables. Initial analyses were on a three-factor (race, age, and sex) design. As indicated in Table 1, however, there were no significant two-way or three-way interactions and no significant sex effects. Therefore, results are presented only for the main effects of race and age. For each test, we examine raw differences between groups as well as associated differences on demographic and academic variables. Given the intact groups used (racial and age groups) we suspected that there would be substantial pre-existing group differences on demographic

[1] Social Position is based on a combination of weighted educational and occupational levels. Father's occupation and education were used to determine social position. When for any reason this information was missing, the mother's occupation and education were used.

Table 2
Racial Differences on the Self-Esteem Inventory (SEI) and the Tennessee Self-Concept Scale (TSCS): Demographic and Academic Variables

Variable	M		F (df)
	Black	White	
SEI data set			
SEI	60.72	66.21	11.81 (1, 364)**
Mother's education	10.57	11.28	6.41 (1, 317)*
Father's education	9.16	10.80	19.14 (1, 288)**
Social position	4.62	4.17	23.69 (1, 364)**

variables that might be logically related to SEI and TSCS differences. Although we are aware of the limitations of adjustment procedures with intact groups, we have presented estimates of group differences (and tests of significance) adjusted for covariates. Readers are advised to regard these results with caution, bearing in mind that it is very difficult to judge the quality of the adjusted scores under these circumstances.

Racial Differences

SEI. Table 2 contains group means and *F* values for examining the main effects of race. The upper half of Table 2 contains raw SEI scores and academic and demographic information collected on the SEI groups. As can easily be seen, white subjects received higher self-esteem scores than black subjects. Indeed, black and white subjects differed significantly on all variables, with white students having higher parental education and social position, higher achievement and IQ scores, and fewer siblings. Intercorrelations of these variables with SEI scores are given in Table 3. The intercorrelations of these variables with the TSCS are also presented in Table 3. All of these variables, with the exception of father's occupation, correlate significantly with SEI scores. Given the initial racial differences on these variables and their significant intercorrelations with the SEI, we attempted to obtain estimates of racial differences in the SEI adjusted for these variables through the use of

Table 3
Pearson Product-Moment Correlations of Self-Concept Measures With Demographic and Academic Variables

Variable	SEI (r)	TSCS (r)
Mother's education	.199**	.129

Raw TSCS Differences	−4.29	1.10 (1, 355)
Differences adjusted for		
Mother's education	−3.25	.44 (1, 313)
Father's education	− .63	.03 (1, 296)
Social position	−2.14	.23 (1, 354)
No. children	−3.78	.68 (1, 343)
Achievement	2.52	.56 (1, 319)
IQ	3.79	.91 (1, 344)

* $p < .01$.

an analysis of covariance. The results of these adjustment analyses are given in the upper half of Table 4. Keeping our earlier proviso in mind, we found that each of these adjustments results in some attenuation of the racial difference in SEI scores. White students, nevertheless, continue to have significantly higher SEI scores when social status or the educational level of either parent is covaried. However, the black-white difference on the SEI is virtually eliminated when either achievement or IQ scores are covaried. Likewise, controlling for the number of children in a student's family substantially reduces the racial difference.

TSCS. A somewhat different pattern of relationships emerges when one examines racial differences in self-concept as measured by the Total Positive Score from the TSCS. These results are presented in the lower half of Table 2. Perhaps most important, there is not a significant difference in the TSCS scores obtained by black and white students, even though this group of white students also comes from significantly more advantaged families, has fewer siblings, and higher achievement and IQ scores. A reinspection of Table 3 reveals that both academic variables are significantly related to the TSCS; however, unlike the SEI, the TSCS is significantly correlated with only one of the demographic variables, father's education. The results of the covariance analyses are presented in the lower half of Table 4. Covarying any of the demographic variables results in a decrease in the racial difference; covarying either of the academic variables results in a reversal of the difference so that the scores of black students are nonsignificantly higher than those of white students.

These two measures, then, yield different results when administered to unmatched groups of black and white students. The SEI reveals racial differences; the TSCS does not. One of the reasons for this difference appears to be the fact that the SEI is correlated with a larger number of race-sensitive demographic variables than is the TSCS. Both measures are consistent, however, in showing the major impact that academic variables, such as achievement and IQ scores, have on self-esteem. As suggested in Table 4, when black and white students are matched for either of these variables, their self-esteem scores do not differ. The results of the initial analysis with the

Table 5

SEI are consistent with those of Bridgette (1970), who found that white students have significantly higher self-esteem scores than black students. We did not, however, replicate Wendland's (1969) findings of higher TSCS scores for black students. The present results represent a 12-point decrease in TSCS scores for black students and a 4-point increase for white students when compared to Wendland's subjects. An explanation of our success in replicating Bridgette's findings but not Wendland's may be that Wendland tested children while schools were still segregated, whereas Bridgette tested them after desegregation had begun.

Grade Differences

SEI. As indicated in the upper half of Table 5, the mean self-esteem score of seventh-grade subjects was slightly higher than that of the tenth-grade group, but the difference is not significant. The two age groups are largely comparable on demographic variables but, as one might expect, the tenth-grade group had a significantly higher achievement level. The tenth-grade group also had higher IQ scores. When the SEI scores are adjusted for each of the demographic variables, the small age difference in SEI remains basically unchanged. Adjusting SEI scores for achievement level, $F(1, 284) = 12.84$, $p < .001$, or for IQ, $F(1, 332) = 3.99$, $p < .05$, does result in significantly higher SEI scores for the seventh-grade group.

TSCS. The scores received by the seventh-grade subjects on the TSCS are significantly higher than those received by older students (see the lower half of Table 5). These two age groups are comparable on all demographic variables except for the number of children in the family, which is higher for the younger group. The achievement level, but not IQ, of the older subjects is higher. Adjusting TSCS scores for parental education or number of children in the family reduces the age difference so that it is no longer significant. The age difference is increased when TSCS scores are adjusted for social position, $F(1, 354) = 3.92$, $p < .05$. And, as in the case of the SEI, adjusting TSCS scores for achievement, $F(1, 219 = 12.77$, $p < .001$, or IQ, $F(1, 344) = 4.42$, $p < .05$, enhances the age effect.

Table 6
Mean Difference Scores (Grade 9 — Grade 7 Scores)

	SEI			TSCS		
	n	*M* Difference	*SD*	*n*	*M* Difference	*SD*
Black males	27	1.11	12.23	20	−5.90	21.84
Black females	31	−.29	14.50	28	−8.86	33.69
White males	42	−.09	16.82	41	−2.63	33.94
White females	28	1.78	13.70	39	−7.21	35.68

Changes in Self-Esteem

The primary purpose of the following analyses was to assess patterns of change in self-esteem as a function of race and sex. Changes in self-esteem were examined in two ways. First, the difference scores (Grade 9 scores − Grade 7 scores) were examined by means of an analysis of variance in which race and sex were the factors. Second, we performed a similar analysis but used the original seventh-grade score as a covariate to control the possible impact that the level of the initial score might have had on the amount of change.

The mean difference scores for both the SEI and TSCS subjects are presented in Table 6. In examining the scores, one should bear in mind that the possible range of scores on the SEI is relatively small (50 to 100), whereas on the TSCS, scores can range from 100 to 500. Changes in SEI scores were small and inconsistent from one race/sex group to another. Changes in TSCS scores were also small, but were consistent in showing a decline from the seventh grade to the ninth grade. The earlier comparison of these subjects as seventh graders with tenth graders showed the seventh-grade students to have significantly higher scores. The present data also suggest that one can expect a decline in TSCS scores from junior to senior high school.

The analyses of variance revealed no main effects for race or sex nor any interaction effects on either the SEI or TSCS difference scores. Furthermore, the covariance analysis for each test was consistent in showing neither race nor sex differences. Finally, the pooled regression for the four race/sex groups was highly significant ($p < .001$) for each of the tests, indicating that the ninth-grade scores were very predictable from seventh-grade scores in all instances.

Discussion

The major conclusion of this study is that it is possible to ensure or preclude findings of racial or age differences in self-esteem through test selection or control of relevant demographic and academic variables. Although it is true that tests such as the SEI and the TSCS purport to measure the same phenomenon, it is also clear that they are differentially related to a number of factors that affect self-esteem. A casual inspection of these two tests discloses only that the SEI has the advantage of being shorter and the TSCS the advantage of being longer. Further examination of the tests reveals them to be similar in content with both tests sampling from a wide range of self-referent statements that are typically assumed to be important in describing the self-concept. The SEI is, however, more highly related to a number of demographic factors and reveals racial differences. The TSCS shows weaker relationships to these variables and does not reveal racial differences. The problem is to determine which self-esteem measure is to be preferred, especially when one is making racial comparisons.

In considering the relative merits of these two instruments, a decision as to which is better cannot be based on a strict judgment of which has greater construct validity, since there is no uncontested, external criterion of self-esteem. Rather, the choice will have to be made on the basis of the network of relationships that exists between each of these tests and other demographic and experiential values.

One might easily argue that the test that appears most culture-free, that has a weaker correlation with conventional indicators of status and social position, should be preferred. This argument would lead to the selection of the TSCS. One might also argue the inverse—that because the SEI is more highly correlated with other conventional measures of status and position, it will be more predictive of success and should, therefore, be preferred. The latter, culture-bound argument implies that one's self-esteem should be, for example, a reflection of socioeconomic status. Although it is reasonable that factors such as parental status or school achievement might contribute to a child's self-esteem, many self-concept theorists and researchers seem to work under the assumption that self-esteem is an important feature of personality and should, therefore, add to the information derived from demographic or academic data (see Block, 1971).

The many problems that plague this area of research point to the need to incorporate a number of methodological and conceptual refinements in future studies of self-concept. We have already alluded to the necessity for care in test selection and control of subject characteristics; studies such as that of Long and Henderson (1968), which compare disadvantaged black subjects with advantaged white subjects, contribute little to the understanding of racial or social class differences in self-esteem. Furthermore, in reviewing studies relevant to the present one (that is, studies that make direct racial comparisons of self-esteem), it becomes clear that not only test and subject characteristics but also contextual variables need to be considered. Specifically, the racial make-up of the school may be an important determinant of the direction of racial differences in self-esteem. Most of the studies (including the present one) that report higher self-esteem scores for white students or no racial differences were completed in integrated settings (Bridgette, 1970; Rosenberg, 1965; Wylie & Hutchins, 1967). Studies that report more positive self-concept scores for black children seem to have been completed in either segregated schools (Baughman & Dahlstrom, 1968; McDonald & Gynther, 1965; Wendland, 1969) or desegregated schools in which blacks were a majority (Powell, 1973; Rosenberg & Simmons, 1971; St. John, 1975; Soares & Soares, 1969).

There is also a need for greater clarity in the definition of self-esteem. This is a particularly difficult problem. The concept of self-esteem has great appeal and is evoked to explain a host of complex behavioral and personality characteristics. It is unlikely that any one of the instruments typically used to measure self-esteem will adequately encompass this complexity. What promise to be more feasible alternatives are greater articulation of and more specificity in the facet of self-concept being measured. Watkins (1978), for example, suggested an approach to self-esteem that attempted to take into account the value system of the person tested. Subjects were asked to rate themselves in various areas of life—for example, social, family, and general happiness—and the responses were weighted by the relative importance of these areas to the subject. Watkins suggested that this procedure might easily be tailored to the particular social or ethnic group under consideration. Wylie and Hutchins (1967), on the other hand, focused on a specific content area, academic self-concept, in testing groups of black and white adolescents whom they had attempted to equate on socioeconomic status and academic ability.

In addition to delimiting self-concept in the preceding and other ways, we also need to be clear as to whether our intention is to measure the individual's self-concept or the individual's pride in his or her race. Although these two ideas may be interdependent, there is no need to assume that they are equivalent either to one another or to the status one's racial or ethnic group has in society (Rosenberg, 1965).

Finally, the truism that intragroup variations are frequently greater than intergroup differences bears periodic repetition for those studying racial differences in self-esteem. Although this does not mean that racial comparisons should not be made, it does mean that global racial comparison will be of limited utility. If one is primarily interested in studying the plight of blacks and other minorities, then it is eminently more useful to investigate the causes and prevention of racism, poverty, and discrimination. If, on the other hand, one is primarily interested in the antecedents of

self-esteem, then another approach is desirable—one that focuses on variations in self-esteem of subjects who are equated on other characteristics that are known to be relevant. Studies of racial differences in self-esteem are not instructive either with regard to the nature of self-concept or racial differences in personality when the groups initially differ in ways that are confounded with race.

Observer Bias in the Attitude Attribution Paradigm: Effect of Time and Information Order

Edward E. Jones, Janet Morgan Riggs, and George Quattrone
Princeton University

Subjects were exposed to an essay taking either a pro or anti stand on the use of minority quotas. They were informed either before or after reading the essay that the writer had or had not been permitted to choose which side of the issue to support. Subjects returned for a second session a week after the first, and their attributions of true attitude to the essayist were again measured. The results replicated previous attitude attribution findings, but the tendency to attribute an essay-consistent attitude when the essay was written under high constraint was much greater when the constraint information appeared *after* exposure to the essay. There was no hint of a sleeper effect and, therefore, no evidence that constraint cues were discounted over time.

The attitude attribution paradigm—diagnosing "true attitudes" from opinions expressed under varying situational pressures—has provided consistent evidence of a tendency to assume correspondence between the expressed opinions and underlying attitudes of a target person acting under high constraint. The data are summarized and discussed in a recent article by Jones (1979). This robust tendency toward observer bias has been referred to by Ross (1977) as the "fundamental attribution error." Ross emphasizes the ubiquity of overattributing personal dispositions to account for behavior and reports the results of several ingenious experiments that carry the phenomenon beyond the realm of attitude attribution per se. Nevertheless, the attitude attribution paradigm stands out because of its historical importance as a basis for the actor–observer divergence proposition (Jones & Nisbett, 1971), and because research within the paradigm has withstood intense scrutiny for artifacts; that is, explanatory alternatives lacking in general theoretical interest.

The present experiment was designed to explore the role of temporal delay in the attitude attribution process, and to determine whether attributions for constrained behavior are affected by the locus of constraint information in the experimental sequence.

The role of temporal delay is of interest because of a clear analogy between the attitude attribution paradigm and the traditional sleeper effect paradigm in attitude change. According to the early formulations of Hovland and his colleagues (Hovland & Weiss, 1951; Kelman & Hovland, 1953), a sleeper effect may occur when a communication is paired with a negative or low credibility source. Over time, their reasoning goes, the discounting information about the source becomes dissociated from the communication, which, therefore, has a delayed effect on attitude change. Gillig and Greenwald (1974) have argued that the evidence for the sleeper effect is suspect. Nevertheless, it seems reasonable that under some conditions, competing pieces of information would have different decay functions in memory. Since the behavior involved in an expressed opinion is presumably more salient than the contextual information about constraining conditions, there is some reason to think that retention of the essay's direction and extremity will be better than retention of the discounting information that it was prepared under highly constraining conditions. The constraint information is viewed as analogous to discounting information about the source in

sleeper effect studies, and degree of correspondence is analogous to attitude change, since it represents a departure from the neutral or typical attitude that presumably would have been attributed in the absence of any information about the target person.

Order of information has been constant in all previous attitude attribution studies. In the natural world, we usually learn about or make surmises about the context of behavior before or during the action itself. Nevertheless, it might be argued that the tendency to overattribute dispositions from constrained behavior may be adequately explained as the effect of recency on recall, since information about the context in the typical attitude attribution study is temporally more remote than the opinion statement from the dependent attribution rating. In the present study, therefore, statement-context and context-statement orders were directly compared. If the statement-context order were to eliminate the fundamental attribution error, this would place severe qualifications on the generality of the effect.

Method

Subjects

Undergraduate volunteers ($N = 79$) participated for money in a study of impression formation. Subjects were run in groups of 12 or less, and each participated in two experimental sessions that were 1 week apart.

Procedure

Session 1. When subjects arrived for the first experimental session, they were told that the experimenter was interested in "how people form impressions of others depending on the information they receive and how this information is conveyed" (video, audio, written, etc.). Subjects were told to expect to receive information about another person through various means in the experimental sessions in which they would be participating.

A booklet containing the following materials was then given to each subject: an essay supposedly written by a target person (male) concerning the use of a minorities quota system in determining college admissions; instructions supposedly given to the target person at the time the essay was written; and a questionnaire to be completed by the subject. The essay was either in favor of or opposed to the use of a quota system in college admission policy. Each essay was approximately 370 words long and contained four arguments in support of the stand taken.

The instructions included in the booklet either gave the target person the freedom to take whatever position he chose on the issue or assigned him a position, pro or anti, to support in his essay. The essay always endorsed the position assigned. Instructions to the target person were prefaced by the statement: "You might be interested in knowing that the essay was written under the following instructions." The target person was then described as being asked to imagine that he was a member of a debating team and was instructed to prepare a series of persuasive essays or opening statements on various opinion issues. Included in these instructions was either the no-choice manipulation, "Today I would like you to write a persuasive essay favoring [opposing] the quota system as a part of college admission procedures," or the choice manipulation, "Today I would like you to write a persuasive essay either in favor of or opposed to the quota system as a part of college admission procedures." Finally, order of presentation of the essay and instructions was varied; the instructions were either presented immediately before or immediately after the essay in the booklet.

To summarize, the three independent variables manipulated in Session 1 were position taken in an essay toward the use of a quota system in college admissions (pro or anti), instructions under which the essay was prepared (choice or no choice), and order of presentation of essay and instructions in the booklet (essay first or essay last). Each subject was randomly assigned to one of the eight experimental conditions.

After reading the material, subjects completed a questionnaire that included evaluation of the target person's attitude toward the use of minority quotas in college admissions and other related issues. These included evaluation of the target person's attitude toward the busing of school children to facilitate integration, attitude toward the use of minority quotas in the hiring of employees, willingness to support actively the implementation of the quota system in college admissions, frequency of discriminatory behavior toward others based on minority membership, and general liberalism–conservatism. The questionnaire continued with several manipulation checks ("How much freedom did the target person have to choose the position or side he took?" "direction and extremity of the target person's essay..."); a final question asked for the subject's own attitude and his or her estimate of the typical undergraduate attitude toward the use of a minorities quota system. Subjects were then asked to return for another experimental session 1 week later. They were directed to talk with no one concerning the experiment during that week.

Session 2. When subjects returned for the second experimental session, they were first asked to recall the information they had received the week before about the target person and were then asked to complete a questionnaire containing several of the dependent measures administered in the first session. It was explained that some subjects might have changed their feelings or forgotten the first week's material over the time interval; therefore, they were urged to record their current impressions of the target person who wrote the essay. To provide suitable justifications for the second session and for rating changes if the subject's current

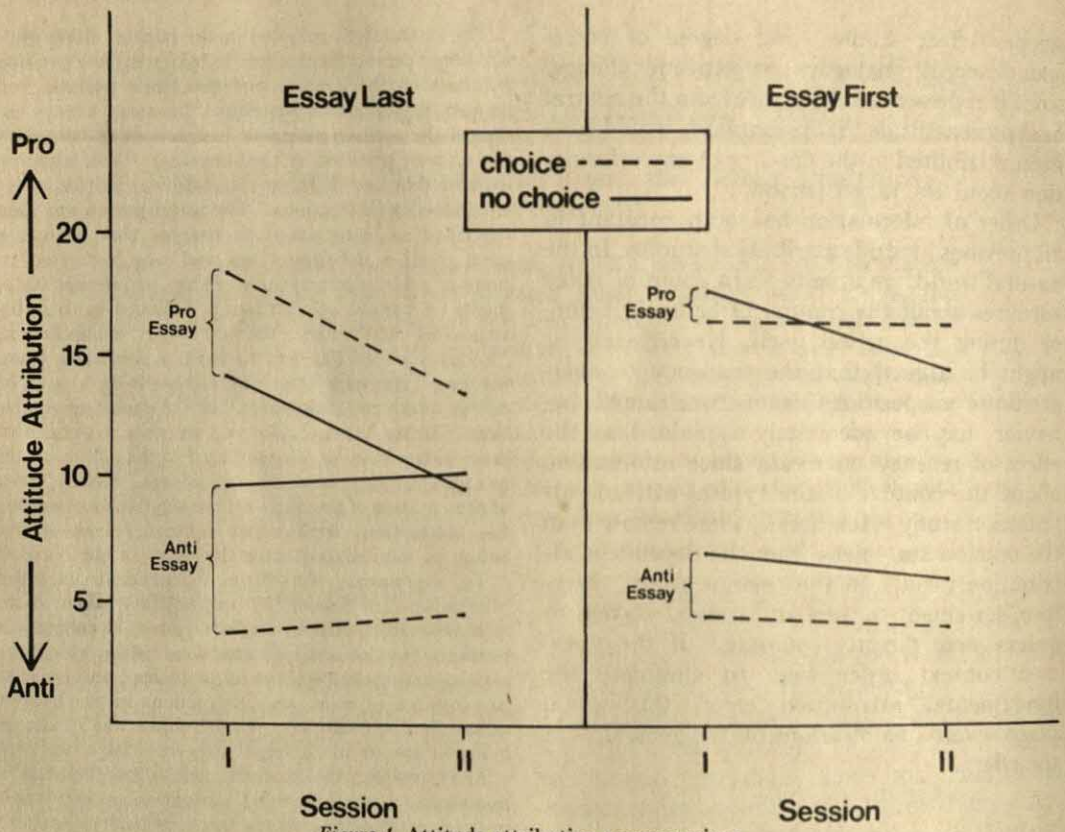

Figure 1. Attitude attribution across sessions.

feelings differed from his or her recalled impression, a 5-minute tape of a supposed interview between the experimenter and target person was then played to provide "additional information." The interview avoided discussion of social issues and described a person who seemed to be a typical college freshman.

Following the tape, subjects were asked to evaluate the target person on a series of interview-relevant dimensions and to reevaluate the target person on the same dependent measures administered previously. This third set of ratings did not differ markedly from the second, although subjects tended to converge toward a more neutral attributed attitude, probably because of the rather bland and noncommittal impression conveyed by the tape. The ratings made prior to the tape in Session 2 are the focus in the subsequent presentation of Session 1–Session 2 differences.

At the close of the second session, subjects were fully debriefed.

Results

The present experiment had two primary goals: (a) to explore the possibility of a sleeper effect or the differential retention of behavioral versus contextual information over time and (b) to investigate the role of information order in leading observers into the "fundamental attribution error." We shall deal with data relevant to both of these goals after evaluating the general evidence on observer bias.

Correspondence and Observer Bias

Previous findings (cf. Jones, 1979) have shown greater correspondence of attitude attribution under choice than no-choice conditions. This was again clearly demonstrated in the present experiment: When the target person was alleged to have a choice in producing the essay read by subjects, he was seen to hold a more extreme attitude toward quota systems in education (in line with the direction of the essay) than when the target person had no apparent choice. The statistical interaction between essay direction and choice was significant in both sessions: Session 1 $F(1, 71) = 20.32$, $p < .001$; Session 2 $F(1, 71) = 8.45$, $p < .01$.

Previous findings of significant correspondence of attribution and essay direction under no-choice conditions were also replicated in both sessions. In Session 1, the no-choice–pro essayist was seen as more in favor of quotas ($\bar{M} = 15.9$) than the no-choice–anti essayist ($\bar{M} = 8.4$), $F(1, 71) = 56.85$, $p < .001$. In Session 2, the tendency was reduced but still significant, $F(1, 71) = 6.14$, $p < .05$. In both sessions target persons with choice were, of course, attributed even more extreme attitudes.

A Sleeper Effect?

Since past evidence suggested that subjects pay more attention to behavior (figure) than its context (ground), it seemed quite possible that behavior in the no-choice conditions would have even more impact as remembered in Session 2 than in Session 1. In other words, there might be a sleeper effect in attitude attribution as a function of forgetting the less salient constraint information more rapidly than the more salient behavior.

The results provide no support for the sleeper effect notion. A repeated-measures analysis of variance showed very little variance ($F < 1.00$) attributable to the crucial interaction between essay direction, choice, and session. In fact, as Figure 1 shows, the observer bias or fundamental attribution error disappears by the second session *if* the context has preceded the essay in the first session. The bias is maintained in the essay-first condition. Clearly, in any event, there is no hint of the kind of sleeper effect when the impact of behavior direction becomes greater over time. If anything, the implications of contextual constraints themselves become stronger over time.

Table 1
Attributed Attitude Toward Quota System in College Admissions (Session 1): Means

Position	Choice		No choice	
	Essay first	Essay last	Essay first	Essay last
Pro	16.3	18.3[a]	17.6	14.1
Anti	4.4	3.8	7.0	9.7

Note. 1 (strongly opposed) to 21 (strongly in favor).
[a] $n = 9$ in this cell; $n = 10$ in all others.

Table 2
Attributed Attitude Toward Quota System in College Admissions (Session 1): Analysis of Variance

Source	*df*	*MS*	*F*
Essay direction (A)	1	2,111.23	159.58**
Constraint (B)	1	38.16	2.88

A × B	1	160.29	12.15**
A × C	1	15.68	1.19
B × C	1	6.12	
A × B × C	1	95.90	7.25*
Within error	71	13.23	

* $p < .01$. ** $p < .001$.

At least this appears to be true when the no-choice context is initially presented prior to the essay.

Effects of Information Order

It is the case that all previous research on attitude attribution has featured a standardized order of information about contextual constraints followed by an opinion statement. Although this probably parallels mundane reality most of the time, an obvious question is whether context is relatively ignored (and behavior relatively emphasized) because of a recency effect. Since the essay or speech is the last piece of information before the crucial rating in the standard paradigm, perhaps its differential influence is a function of its differential salience in memory.

The present results clearly speak against such a recency effect. In fact, whether one looks at the data from Session 1, Session 2, or combines the data from both in a repeated-measures analysis, the essay has *greater* impact when it comes first. For convenience of exposition we shall concentrate on the Session 1 data, though we have already seen (in Figure 1) that the differences of interest become greater in Session 2.

Tables 1 and 2 present the means and analysis of variance summary, respectively, of ratings on a 21-point scale of attributed attitude toward "the quota system in college admissions." It can be seen that there is a significant triple interaction, $F(1, 71) = 7.25$, $p < .01$, that focuses on the greater spread between no-choice–pro and no-choice–anti

Table 3
Judged Essay Direction, Perceived Freedom, and Confidence: Means

Measure	Essay first				Essay last			
	Pro		Anti		Pro		Anti	
	C	NC	C	NC	C	NC	C	NC
Judged direction and extremity[a]	19.2	19.6	2.9	3.5	18.2	16.4	3.9	5.2
Perceived freedom[b]	3.4	16.2	4.2	14.6	4.6	20.3	2.9	20.5
Confidence[c]	17.3	14.7	16.3	15.6	14.0	10.3	18.5	12.2

Note. C = choice; NC = no choice.
[a] 1 (essay strongly opposed) to 21 (essay strongly favored).
[b] 1 (complete freedom) to 21 (no freedom).
[c] 1 (low confidence) to 21 (high confidence).

ratings when the essay is presented first rather than last. This is also apparent in Figure 1 (see no-choice, Session 1 means). The triple interaction is larger than the simple Direction × Order interaction because order of information has no impact within the choice conditions.

Related traits. The reader will recall that subjects also rated the target person on related opinion issues ranging from busing to general liberalism. These ratings were summed, and an analysis of variance revealed a pattern of F ratios almost identical to those on the most directly relevant admissions quota question. The triple interaction was again significant, $F(1, 71) = 4.43$, $p < .05$, as was the simple Order × Direction interaction, $F(1, 71) = 5.70$, $p < .05$. On both the direct trait rating and the related ratings composite, the simple effect of essay direction was significant regardless of when the context was mentioned, though the difference was significantly greater when the essay preceded the explanation of context.

Supporting perceptions. In approaching the question of why the attribution error is greater when the essay comes first, it is important to note that the essay-first subjects appear to see the behavior and the situation differently than the essay-last subjects. When asked to judge the extremity of the essay, compared to the essay-last subjects the essay-first subjects rated the pro essay as more in favor of and the anti essay as more opposed to the quota system; for the interaction between order and direction, $F(1, 71) = 10.60$, $p < .01$.

Not only was the essay judged more extreme when it preceded the context, but the essayist was judged to have greater freedom when the no-choice context was mentioned after exposure to the essay. The fact that this effect of order on perceived freedom differentiated the two orders only in the no-choice conditions is reflected in a significant Constraint × Order interaction, $F(1, 71) = 5.25$, $p < .05$.

In line with these two findings, subjects in the essay-first condition were significantly more confident of their attitude attributions than were subjects in the essay-last condition. This difference was especially marked in the no-

choice conditions, $F(1, 71) = 6.94$, for order within no choice.

The means and analysis of variance summaries on these items are in Tables 3 and 4, respectively.

Own and perceived typical attitude. Subjects were finally asked to rate their own attitude toward the quota system in college admissions as well as that of the average undergraduate. In previous attitude attribution studies, the subjects' own subsequently measured attitude has sometimes, but by no means always, been positively related to their attributions to the target person (cf. Jones, 1979). In the present study a most distinctive interaction was discovered. This is portrayed in Figure 2. In all but those no-choice conditions in which the essay was presented first, subjects showed a contrast effect: Those exposed to a pro essay rate themselves as more against quotas than those exposed to an anti essay. However, this trend was markedly reversed in the no-choice, essay-first conditions. The resulting triple interaction (Essay Direction × Constraint × Order) was highly significant, $F(1, 70) = 15.05$, $p < .001$. The same trends are also present in the data on perceived typical attitude. The triple interaction was again significant, though not quite as strong: $F(1, 70) = 7.75$, $p < .01$.

Figure 2 also indicates the within-cell correlations between attributed attitude and own attitude. None of these correlations was significant, and the pattern of the larger ones is uninterpretable and unrelated to the distribution of means as a function of the independent variables. Thus we are faced not with a general tendency for attributed attitude to follow own attitude or to contrast with own attitude, but a tendency for the various experimental conditions to have systematic effects on attributed attitude, own attitude, and perceived typical attitude.

The most reasonable accounting for the errant findings in the no-choice, essay-first cells, is attribution to chance: The significant

interactions on the own-attitude data may represent a Type I error of accidental significance. To shed light on this possibility, 28 additional subjects were run in the four no-choice conditions (i.e., retaining the variations in essay direction and information order). Although the distinctiveness of the essay-first conditions was not nearly as striking in this sample, the same general pattern was observed. In the new sample the simple interaction between order and essay direction was not significant, but adding the two samples together produced a highly significant interaction, $F(1, 63) = 22.77$, $p < .001$. This seems too robust to be explained away as a chance vagary of the random assignment of subjects. We can only conclude that some aspect of the experimental experience caused subjects to evaluate their own attitudes differently as a function of the condition to which they were assigned.

Discussion

The results of the present experiment provide no support for any speculations concerning a sleeper effect in attitude attribution. Reasoning by analogy with Hovland and Weiss's (1951) finding that in delayed recall subjects remember the content of a message better than discounting characteristics of the source, we speculated that the positions of an author might be better recalled after a week's time than the circumstances under which the author prepared the statement. In the present experiment subjects returned a week after their exposure to a pro or anti essay on minority quotas and were asked to rate the true attitude of the writer without further exposure to his essay or the constraint context in which it was allegedly prepared. Subjects previously run in the high-choice condition showed little or no change in their unequivocal attitude attributions. In contrast, subjects initially exposed to a highly constrained target person showed the customary observer bias in the first session, but this dissipated completely in the second session *if* the contextual information had preceded the essay. When the essay was presented first, there was some regression to a neutral attribution by the second session, but much of the biased attribution remained. There was clearly no evidence for a sleeper effect in any condition; on the contrary, when there is any change over time (i.e., in the no-choice, essay-last conditions), the attribution error is diminished rather thean augmented.

Prior evidence for a sleeper effect in attitude change studies has already been severely challenged by Gillig and Greenwald (1974), though their conclusion has in turn been questioned by Gruder et al. (1978). The latter authors suggest that absolute sleeper effects (actual increases in attitude change over time) are to be expected only when there is no immediate attitude change in a "discounting cue" group. They reason that immediate attitude changes can be expected to decay with time, and such decay would countervail against the sleeper effect. The results of their two experiments provide strong evidence in favor of their view. To translate these concerns into terms relevant for the attitude attribution paradigm, the no-choice context information may be viewed as the discounting cue and the attribution of an attitude that is more "pro" or more "anti" than the perceived typical attitude may be viewed as attitude change. Following the logic of Gruder et al., then, the initial existence of observer bias in the no-choice conditions decreases the likelihood that an absolute sleeper effect would be observed: Such an effect would have to operate against the general tendency for attitude attributions to regress toward the neutral point or the perceived typical attitude.

The present results are not even consistent with the possibility of a *relative* sleeper effect—when the effects of discounted material are relatively more persistent than the effects of undiscounted material. There was, in fact, no discernible decay of effect in the undiscounted (choice) conditions, whereas a clear decay was apparent in one of the discounted conditions (no-choice, essay-last). In contrast to the possibility that the essay, because of its initial salience, would retain its impact better than information about constraint, the direction of the essay seemed to be ignored by the average subject in the no-choice, essay-last condition. This convergence over time (see Figure 1) may reflect regression to the mean, but it should be noted that there was no such convergence in the essay-first conditions. It is still necessary, then, to account for differential regression as a func-

tion of the position of the discounting cue (no-choice instructions) during Session 1.

It should also be noted that the present attitude attribution paradigm differs from the typical sleeper effect paradigm in partially reinstating both the communicator and his "message." Thus in the typical sleeper effect study, the delayed measure of attitude is taken in a separate experimental context, and no mention is made of the initial experimental session. In the present study, however, it was necessary to remind subjects of the prior experimental session and the target person whom they would again be asked to judge. This is *not* analogous to the reinstatement condition of Kelman and Hovland (1953), in which subjects were reexposed to the discounting cue itself (a description of the communicator that manipulated his credibility). Nevertheless, the inescapable partial reinstatement involved in bringing to mind the previous week's session may have somehow muted the sleeper effect.

The most striking results of the present experiment are those associated with the effects of information order. Although the fundamental attribution error is demonstrable whether the essay follows or precedes the information about constraint (no choice), it clearly is strengthened when the essay is read prior to the constraint information. In fact, there was no significant difference between attributions in no-choice and choice conditions when the essays came first (Essay direction $\times$ Order interaction, $F = 2.06$, *ns*). Also, there was little or no decay in the attribution effects over a week's time. It appears that the no-choice information is virtually ignored when the subject has earlier been exposed to a strong pro or anti essay. Why might this be the case?

Our findings are reminiscent of the perseverance effect identified by Ross, Lepper, and Hubbard (1975). These investigators found that both actors' and observers' impressions persisted when their basis was subsequently discounted. The perseverance effect has been explained in terms of a cognitive consolidation process wherein the initial impression is buttressed through a reaching out for supportive data in remembered prior experiences, or through an initial salience of confirmatory associations. In the present experiment, subjects in the essay-first conditions presumably assume at first that the essay is written in the absence of clear-cut constraints and therefore represents the true viewpoint of the writer. Their impression of the writer's attitude toward minority quotas in education is readily buttressed by associations to related attitudes and personality attributes that are automatically inferred. The readers will recall that inferences about related attributes (toward busing, etc.) were significantly more consistent with the essay when it preceded the context than when the essay was last.

When the essay-first subjects then learn that the essay was written under highly constraining conditions, they make an adjustment in their assessment of attitudinal extremity, but the buttressing cognitive work they have already accomplished renders this adjustment insufficient. (Indeed, it is not even statistically significant.) In the essay-last conditions, on the other hand, the adjustment is more adequate and the modest (but still significant) tendency toward overattribution is accompanied by a modest amount of cognitive buttressing. The perseverance explanation, then, implies that the initially attributed attitude remains attributed (or is possibly reattributed) as a necessary implication of the associated attitudes that have already been cognitively constructed by the subject. This would not be the first time that the origins of an inference have been disregarded once the inference is made, and new or different origins have been assigned. Snyder and Frankel (1976) for example, showed that emotional dispositions are inferred to account for emotional behavior that was itself previously inferred from an arousing context.

But what shall we make of the distinctive tendency for the subjects' own attitudes, and their estimates of the perceived typical attitude, to vary positively with the attitude attributed to the essay writer *only* in the no-choice, essay-first conditions? We know from the correlational patterning (and the total lack of any overall correlation between own and attributed attitude—overall $r = -.099$) that this distinctive relationship is clearly produced by the independent variables and their particular order. The one explanation that occurs to us involves a mechanism of consistency-maintaining cognitive work not unlike the well-known strategies of dissonance reduction.

The subjects who read a pro-quota essay, for example, who make a strong attribution and then learn that the writer had no choice, are in a situation of dissonance or inconsistency. They have been "taken in." They have made an inference that is not warranted because of the information they belatedly learn about the context. This may be dissonant or inconsistent with the subjects' desire to see themselves as sophisticated and capable of seeing when someone (in this case the essay writer) does not really mean what he says. Faced with this mildly unpleasant challenge to their self-concept, the subjects may attempt to rationalize their premature commitment by shifting their conception of the typical attitude and of their own attitude. After all, if the essay is at or near the consensus position, it is perfectly reasonable to assume that the essay writer really believed what he said—even though there is a reason to discount the essay. In this way, subjects are able to maintain their attributional commitment for a reason that is not vulnerable to the new, discounting information.

A dissonance account is also consistent with the fact that little attribution decay is observed from Session 1 to Session 2 in the no-choice, essay-first conditions (see Figure 1). If the attribution were buttressed by similar attributions about the self and typical other, then one would expect the attributions to be quite stable over time.

Regardless of the eventual explanation for the strong order effects observed in the present experiment, it is clear that the "fundamental attribution error" is enhanced when discounting information follows the formation of an unequivocal impression. It goes without saying that observer overattribution under conditions of constraint is more than an effect of the subject's most recent exposure to the target person's behavior.

Prediction of Behavior From Beliefs: An Extension and Test of a Subjective Probability Model

James Jaccard and Richard Knox
Purdue University

David Brinberg
University of Illinois

A model for the prediction of behavior from beliefs was tested in the context of voting behavior in the presidential election of 1976. A two-wave panel design was used in a field survey in which voting behavior was predicted from beliefs about candidates in accord with a recent subjective probability model. Results supported the model, yielding an average correlation between predicted and obtained voting behavior of .75. The average correlation between predicted and obtained voting intention was .84. The ability of the model to predict behavior and behavioral intentions was relatively unaffected by the educational level of the respondent and the type of beliefs under consideration.

A major concern of social psychology has been the prediction of social behavior. Researchers have used measures of attitude (e.g., Wicker, 1969), norms (e.g , Schwartz, 1973) and personality traits (e.g., Mischel, 1968) in the attempt to achieve accurate behavioral prediction—all with mixed success. Dulany (1968) presented an approach to behavioral prediction based on behavioral intent. According to this perspective, a person's behavior (at least most behaviors of concern to social psychologists) is largely a function of his or her *intention* to perform that behavior. Research by Dulany and others (e.g., Ajzen & Fishbein, 1973) has observed strong relations between behavioral intentions and overt behavior. Conceptual discussions of the relationship between these two variables have been presented by Dulany (1968) and Fishbein and Jaccard (1973).

A number of theorists have attempted to extend this work by specifying factors that determine behavioral intentions. A number of models of the relationship between intentions and psychological variables have been presented in the context of attitude research (Fishbein & Ajzen, 1975), verbal learning (Dulany, 1968), cross-cultural research (Triandis, 1974), and consumer psychology (Sheth, 1973). Each of these approaches is based on the general linear model, in which a set of predictor variables (e.g., attitudes, norms) are weighted and summed to yield an overall prediction of behavioral intent. Generally speaking, the types of predictor variables used have been similar across the various theories.

An alternative approach to understanding the relation between behavioral intentions and psychological variables has been presented by Jaccard and King (1977). These theorists were concerned with the relationship between beliefs and behavioral intentions. A belief was defined as a perceived relation between two "objects." The term *object* was used in its most generic sense, so that it could refer to a person, a behavior, an attribute, a goal, or some concept. Belief strength referred to the subjective probability linking the two objects. For example, in the belief statement, "Smoking cigarettes causes cancer," belief strength refers to the individual's perceived probability that "smoking cigarettes causes cancer." This probability may range from .00 to 1.00. A behavioral intention was defined as a perceived relation between oneself and some behavior. Characterizing this relation is also a subjective probability. For example, the statement, "I intend to vote for Gerald Ford" consists of a perceived relation between "myself" and the

behavior of voting for Gerald Ford. The subjective probability linking these two objects may vary from .00 ("I definitely intend not to vote for Gerald Ford") to 1.00 (I definitely intend to vote for Gerald Ford).

A behavioral intention, according to Jaccard and King, does not differ in its basic structure from any other belief. However, it does possess certain characteristics that distinguish it from other beliefs: (a) it always links a person with some action, (b) it always refers to future behavior, and (c) it is usually correlated with overt behavior (Dulany, 1968; Fishbein & Ajzen, 1975). These characteristics suggest that it would be useful to more fully understand this "special" belief and its relation to other beliefs.

Given that both beliefs and behavioral intentions can be conceptualized as subjective probabilities, Jaccard and King (1977) attempted to extend the work of Wyer (1974) using a model relating these subjective probabilities. Specifically, Wyer (Wyer & Goldberg, 1970; Wyer, 1970, 1974) tested and found support for the following equation as a model of relations among beliefs:

$$P_A = P_B P_{A|B} + (1 - P_B) P_{A|\overline{B}}, \quad (1)$$

in which P_A = the subjective probability that Proposition A is true, P_B = the subjective probability that Proposition B is true, $P_{A|B}$ = the subjective probability that Proposition A is true given that Proposition B is true, and $P_{A|\overline{B}}$ = the subjective probability that Proposition A is true given that Proposition B is not true. Jaccard and King (1977) attempted to extend this model to the analysis of behavioral intentions by rewriting Equation 1, substituting subjective probabilities characterizing a behavioral intention:

$$P_I = P_B P_{I|B} + (1 - P_B) P_{I|\overline{B}} \quad (2)$$

in which P_I = a person's intention to perform a behavior (e.g., vote for Gerald Ford), P_B = a person's perceived probability that Proposition B is true (e.g., Gerald Ford favors reduced government spending), $P_{I|B}$ = a person's perceived probability that he or she would perform the behavior, given that Proposition B is true, and $P_{I|\overline{B}}$ = a person's perceived probability that he or she would perform the behavior, given that Proposition B is not true. A discussion of the conceptual relationship between this model and the models of Fishbein (1972) and others has been presented by Jaccard and King (1977); hence, it will not be considered here. The difference between the two conditional probabilities, $P_{I|B} - P_{I|\overline{B}}$, was termed the psychological relevance of a belief for a behavioral intention. When this difference is large, B may be said to be psychologically relevant to the intention (e.g., a person would vote for Gerald Ford if he favored reduced government spending but would not vote for Gerald Ford if he did not favor reduced government spending). Conversely, when the difference between these two conditional probabilities is low, B may be said to be psychologically irrelevant to the intention (e.g., a person would vote for Gerald Ford regardless of whether or not he favored reduced government spending). In general, a change in a belief will produce a change in a behavioral intention to the extent that the difference between the two conditional probabilities is large.[1]

Jaccard and King (1977) presented data in the context of two experiments that supported the model in Equation 2. Wyer (1970, 1974, 1976) presented data that are consistent with Equation 1. All of these tests, however, dealt with a restricted range of subjects (viz., college students), and the utility of these models has yet to be demonstrated with a more heterogeneous population in a field setting. The purpose of the present investigation is three-fold. (a) To extend previous research by Wyer in an attempt to specify the relationship between beliefs and behavior instead of just the relation of beliefs to beliefs. This involves the incorporation of the concept of behavioral intention into Wyer's model. (b) To test the generality of Wyer's model in the context of an application of the intention model to a noncollege population. Specifically, the predictability of the model is evaluated as a function of the education of respondents. Several theorists (e.g., Bem, 1970) have suggested that models of belief consistency

[1] This assumes that a change in P_B does not affect $P_{I|B}$ or $P_{I|\overline{B}}$. For a discussion of this issue and the model's implication for understanding *changes* in behavioral intentions, see Jaccard and King (1977).

have greater validity for bright college students and intellectuals than for the majority of the population. If such suggestions are correct, then the model should predict better for high versus low education respondents. (c) To investigate psychological factors (e.g., wishful thinking) that may affect the predictability of the intention model.

Method

Respondents

Respondents were 119 males and females living in a Midwestern community of moderate size. Sampling procedures were designed to obtain a heterogeneous sample in terms of education with an approximately equal number of Democrats, Republicans, and Independents. Respondents were contacted by phone and administered a brief phone survey. On completion, they were asked if they would be willing to complete a longer survey in their home. The goal of the sampling procedures was *not* representativeness, but rather heterogeneity, so as to achieve a more stringent test of the generality of the model. The final sample consisted of 54 males and 65 females who ranged in age from 23 to 56 with a mean age of 34.6. Education level varied from less than a high school education to a professional degree, with 34 respondents having not completed high school and 85 respondents with a high school degree or more. A total of 36 Democrats, 48 Republicans, and 34 Independents were interviewed (one individual did not complete the party identification question). Refusals to participate in the final survey were relatively low, being less than 10% of those initially contacted.

Materials

The home interviews took approximately 1 hour to complete. During the first stage of the interview, the interviewer presented an oral introduction to the study and a standardized set of instructions concerning the questionnaire. The respondent then filled out a practice section. This section contained examples of each type of scale and served to anchor the endpoints and eliminate any "warm-up" effects from the data; in addition, the interviewer could detect any misunderstanding of scales prior to actual data collection. The entire interview schedule was self-administered. This probably minimized any effect of "interviewer" on the subject's responses. The interviewer did, however, remain in the house while the respondent was completing the questionnaire to answer any questions the respondent might have.

On the basis of reviews of national magazines, local newspapers, and campaign materials distributed by the Democratic and Republican parties, a set of 17 issues was compiled (e.g., abortion and reduced government spending). A list of these issues is presented in the results section of this article. Data were collected to test Equation 2 for the presidential election. Specifically, for each candidate, respondents provided estimates of P_B, $P_{I|B}$ and $P_{I|\bar{B}}$ for each of the 17 issues. Examples of the statements used to measure these parameters are as follows. P_B = Jimmy Carter favors reduced government spending, $P_{I|B}$: Suppose Jimmy Carter did, in fact, favor reduced government spending. How likely is it you would vote for Jimmy Carter, $P_{I|B}$: Suppose Jimmy Carter did *not* favor reduced government spending. How likely is it you would vote for Jimmy Carter. Each statement was rated on a 21-point unlikely–likely scale ranging from 0 to 100 with a midpoint of 50. Scores were converted to probability units by multiplying each score by .01. These three measures were obtained for each candidate for each of the 17 issues, yielding 102 questions. Behavioral intention (P_I) was ascertained by asking each respondent the probability that he or she would vote for Jimmy Carter and Gerald Ford on a 21-point unlikely–likely scale. A behavioral intention measure was independently obtained for both candidates.

In addition to the above measure, evaluations of each of the 17 issues were obtained on a 7-point bipolar semantic differential scale, with good and bad as the endpoints. A number of demographic variables were also ascertained, including party identification (using the traditional measure of Berelson, Lazarsfeld, & McPhee, 1954), education, religion, self-reported liberal–conservativeness, age, and marital status. In addition, a number of general beliefs about the Democratic and Republican parties were measured. The order of all items was (a) evaluations of each of the 17 issues, (b) beliefs about the Democratic Party, (c) beliefs about the Republican Party, (d) belief strength (P_{Bi}) that Jimmy Carter favors each of 17 issues, (e) belief strength that Gerald Ford favors each of 17 issues, (f) demographics, (g) behavioral intentions (P_I), (h) additional attitudinal and background variables, and (i) the conditional probabilities, $P_{I|Bi}$ and $P_{I|\bar{B}i}$. Note that measures pertaining to each of the parameters of Equation 2 were separated so as to reduce the possibility of respondents perceiving consistencies among them.

Questionnaires were administered approximately 1 week prior to the election. One day after the election, respondents were recontacted and asked if they had voted and, if so, for whom. These self-reports served as estimates of voting behavior.[2]

Results

Reliability of Measures

To ascertain test–retest reliabilities of the probability scales used in the present investigation, a number of items were repeated at the end of the questionnaire. The average test–

[2] Research in political science has tended to indicate that such self-reports of voting behavior are veridical (cf. Campbell, Converse, Miller & Stokes, 1960; Fishbein & Coombs, 1974).

retest correlation of these items was .93, indicating that the scales were relatively reliable. In addition, a number of checks were made to ensure that subjects' responses were not artificially correlated by means of method variance (Campbell & Fiske, 1959). For example, it was assumed a priori that belief strength in two statements, (a) Jimmy Carter is in favor of a constitutional amendment to ban abortion and (b) Jimmy Carter favors reducing the defense budget, should be theoretically uncorrelated (i.e., knowing an individual's score on the first belief should not be predictive of his score on the second belief). Any correlation between these two beliefs would, therefore, reflect common method variance. The correlation between these beliefs was .04 (*ns*). Similar comparisons on a total of 10 belief statements (5 comparisons per candidate), assumed to be uncorrelated a priori, yielded an average absolute correlation of .08.[3] Other data, which indicate that responses are not artificial, are presented in a later part of the Results section.

Prediction of Behavior from Behavioral Intention

To test the relation between behavioral intention (P_I) and voting behavior, a point biserial correlation was computed between P_I and behavioral score (1 = voted for the candidate, 0 = did not vote for the candidate) for each candidate separately. The correlation between stated intention to vote for Carter and observed voting behavior was .87, $p < .01$. The corresponding correlation for Ford was .85 ($p < .01$). These correlations did not differ across a number of individual difference variables (e.g., education and religion) and indicate a relatively strong relation between intentions and behavior.

Prediction of Behavioral Intention from Beliefs

To test the model of behavioral intention proposed by Jaccard and King (1977), a predicted P_I score was derived in accord with Equation 2 for each subject and each of the 17 issues. Table 1 presents the correlation of each of these predicted intentions ($\hat{P}_I$) with behavior and with the observed intention to vote for Carter and Ford. In terms of predicting

[3] Obviously, such a test for method variance assumes the underlying assumption of uncorrelated variables is veridical. Details of the additional comparisons for method variance can be obtained by writing the authors.

voting behavior (VB), the correlation between $\hat{P}_I$ and VB ranged from .68 to .80 with a mean r to Z transformation of .75. All correlations were significant ($p < .01$) and did not vary appreciably across issues or candidates. In terms of predicting behavioral intention, the correlation between predicted and observed intention ranged from .76 to .88, with a mean of .84. Strictly speaking, if Equation 2 is valid, then no curve-fitting parameters should be required to predict observed intention from the predicted intention score. In other words, a regression analysis should yield a slope of 1.0 and an intercept of 0. The appropriate slopes and regression weights were computed for each belief. In no case did the observed slope differ significantly from 1.0 nor did the intercept differ significantly from 0. Finally, in no case did the correlation with P_I of any individual parameter of the model (i.e., P_B, $P_{I|B}$, $P_{I|\bar{B}}$, $P_{I|B} - P_{I|\bar{B}}$) exceed the correlation between P_I and $\hat{P}_I$. The correlation of P_I with each P_B ranged from $-.45$ to .67 with an average absolute correlation of .19; for P_I with $P_{I|B}$ the correlations ranged from .49 to .86 with an average correlation of .79; for P_I with $P_{I|\bar{B}}$ the correlations ranged from .50 to .86 with an average correlation of .75; for P_I with $P_{I|B} - P_{I|\bar{B}}$ the correlations ranged from $-.24$ to .45 with an average correlation of .16; for P_I with $P_B P_{I|B}$ the correlation ranged from .29 to .81 with an average correlation of .64; for P_I with $(1 - P_B)P_{I|\bar{B}}$ the correlations ranged from .05 to .70 with an average correlation of .45.

In terms of prediction, the full model presented in Equation 1 was a consistently better predictor of the P_I than any component of the equation considered in isolation. This is reflected not only in the correlational analyses above but in other indices of goodness of fit. The true superiority of the full model is probably underestimated due to the fact that the increased number of parameters and combinatorial rules result in greater degrees of measurement error than the correlations based on single components.

In addition to the correlational analyses above, the absolute difference between P_I and $\hat{P}_I$ was computed for each subject on each belief. The mean discrepancy score for each belief is presented in Table 1. Discrepancy scores ranged from .12 to .18, indicating little variability in predictability across beliefs. However, these discrepancy scores did differ significantly from perfect predictability (i.e., a hypothetical discrepancy mean of zero). This is not surprising, considering measurement and experimental error in the parameters of the model.

To test the generality of the model across individuals, the sample was divided into two groups: (a) high education (high school graduate or more) and (b) low education (did not complete high school). For the high education group, the correlation between $\hat{P}_I$ and VB ranged from .63 to .80, with a mean of .74. Similarly, the range of correlations between P_I and $\hat{P}_I$ was .77 to .91, with a mean of .85. In no case did the slope differ significantly from 1.0, and in only one case did the intercept differ significantly from 0. For the low education group, the results were comparable. The correlation between $\hat{P}_I$ and VB ranged from .65 to .84, with a mean of .75. The correlation between P_I and $\hat{P}_I$ ranged from .60 to .88, with a mean of .80. In no case did the slope differ significantly from 1.0 nor the intercept from 0. Although the difference in correlations between the two groups is not large, there is a consistent tendency for the model to predict better for high versus low education subjects. Out of 34 correlations (17 for each candidate), the correlation coefficient between P_I and $\hat{P}_I$ was higher (albeit, nonsignificantly so) for the high education group on 27 of them. This was significant ($p < .05$) via a sign test. More important, the standard error of estimate was lower for the high education group on all 34 relations. Thus, there was a tendency for the model to predict consistently better for high versus low education respondents.

In addition to the above correlation analyses, an analysis of mean $|P_I - \hat{P}_I|$ scores was performed. Specifically, a Hotelling T^2 test was performed comparing high versus low education respondents on the vector of mean discrepancy scores for each belief. For the 17 beliefs concerning Carter, a T^2 of 13.95, $F(17, 101) = .71$, *ns*, was observed, whereas for the 17 beliefs concerning Ford, a T^2 of 27.54, $F(17, 101) = 1.40$, *ns*, was observed. Thus, the analysis of mean absolute dis-

Reduced government spending	.46	.59	.52	.35	.17	.61	.75	.67	.46	.21

Note. Observed P_I Carter = .41; observed P_I Ford = .61; N = 119.

crepancy scores yielded no differences in predictability as a function of education. In general, mean discrepancy scores for each separate educational group were similar to those presented in Table 1 for the total sample.

Table 2 presents mean scores for the components of the behavioral intention model as well as for $\hat{P}_I$. The observed mean P_I for Carter was .41, whereas for Ford it was .61. It can be seen that the model also tended to accurately predict mean behavioral intention scores. The range of differences in mean $\hat{P}_I$ versus mean P_I was −.09 to .07, with a mean of −.01. In no case did the observed mean differ significantly from the predicted means.

From an applied perspective, Table 2 has some interesting implications. First, one can examine the mean belief strength scores (P_B) for each candidate. For each of the 17 issues, the candidates took specific positions during the course of their campaigns. It is interesting to note that in every case the direction of the difference in means is consistent with the stands taken by the candidates. For example, relative to Ford, Carter was more in favor of busing, amnesty, registration of guns, a national health system, labor unions, a guaranteed annual income, reducing the defense budget, and closing tax loopholes for big business. These differences were reflected in the mean P_B scores. This suggests, contrary to many perspectives (e.g., Campbell, Converse, Miller, & Stokes, 1960; Sears 1969), that voters may have considerable information about candidates and that they may accurately perceive differences between them.

Examination of mean psychological relevance scores (i.e., $P_{I|B} - P_{I|\bar{B}}$) indicates the following beliefs as being the most important for influencing behavioral intentions: (a) reducing inflation by policies encouragning unemployment, (b) closing tax loopholes for big business, (c) being trustworthy, (d) being experienced, (e) clearly stating one's positions, and (f) reduction of government spending. However, it should be noted that in general, the difference between the conditional probabilities for each of these beliefs was relatively small (approximately .20). This probably reflects the fact that change in any one belief about a candidate would not have a great impact on voting intention due to the importance of several other beliefs in the determination of voting intentions. However, changing several beliefs may have a dramatic impact on voting intention and behavior. For further

discussion of this issue, see Jaccard and King (1977).

Additional Factors Affecting Model Predictability

In addition to individual differences in model predictability, a set of analyses was undertaken to determine whether the type of belief under consideration influenced the ability of the subjective probability model to predict intentions. For each belief statement, a predictability index was defined as $|P_I - \hat{P}_I|$, for each individual. McGuire (1960a, 1960b, 1960c) has suggested that such variables as (a) the favorability of the beliefs in question (i.e., wishful thinking) and (b) how "affectively charged" beliefs are, may affect the logical relations between beliefs. Similarly, these variables may affect the predictability of the intention model.

To test the extent to which model predictability is related to how "desirable" the belief in question was, the predictability index was correlated with the evaluative ratings of each issue (on a 7-point semantic differential good–bad scale scored +3 to −3). In general, the correlations were low and nonsignificant. The range was −.19 to .11 with an average correlation of −.02.

In addition, the correlations between the predictability index and the absolute value of the evaluative ratings was also computed for each belief statement. This analysis would indicate the extent to which model predictability is influenced by how "affectively charged" the issue is, irrespective of the direction of that affect (positive or negative). Again, the correlations were typically low, with a range of −.20 to .15 and an average correlation of −.03.

These correlations must be interpreted cautiously, since they involve the correlation of one variable with a difference score. It is a well-known fact that difference scores can be highly unreliable and would tend to mask a significant true correlation via measurement error. However, "test" measures used in the study generally indicated high reliability, suggesting this may not be a problem. Nevertheless, no direct data are available to estimate the reliability of the difference score.

Discussion

The present data support the model of behavior and behavioral intention based on Equation 2. The average correlation between voting behavior and voting intention was .86. The strength of this relationship did not vary as a function of numerous individual difference variables. In addition, the average correlation between predicted versus obtained voting intention was .84. In general, regression analyses indicated that ad hoc curve fitting procedures were unnecessary for prediction of voting intention (i.e., intercepts did not differ significantly from 0.0 and slopes did not differ significantly from 1.0). Furthermore, the strength of the relationship between predicted and observed voting intention did not vary appreciably as a function of the respondent's education. However, there was a tendency for the model to predict consistently better for high versus low education respondents. Predictability of the model was found to be unaffected by the desirability of the belief on which it was based or how "affectively charged" the belief was viewed. These data indicate that Wyer's (1970) probability model can be applied to the understanding and prediction of behavior as well as beliefs.

The present model of behavioral intention has a number of interesting implications for theoretical and applied research. First, it represents an interesting alternative to models of behavioral intention presented by Fishbein (1972), Triandis (1974), Sheth (1973), and others. As noted earlier, each of these approaches is based on the general linear model in which a set of predictor variables (e.g., beliefs) are weighted and summed to yield an overall prediction of behavioral intent. Each of these models relies on a regression equation for its basic format. In contrast, the present model does not rely on such an approach and circumvents a number of problems raised in the context of correlational approaches (see Jaccard & King, 1977, for an elaboration).

Second, the present model has a number of interesting implications for changing behavioral intentions. If $P_{I|B}$ and $P_{I|\bar{B}}$ are held constant, then the following relation should hold:

$$\Delta P_I = \Delta P_B(P_{I|B} - P_{I|\bar{B}}), \qquad (3)$$

in which ΔP_I = the change in the subjective probability characterizing the behavioral intention, ΔP_B = the change in the subjective probability characterizing the belief, and all other terms are as previously defined. If a persuasive message effectively changes P_B, its corresponding influence on P_I will be proportional to the difference $P_{I|B} - P_{I|\overline{B}}$. More important, Equation 3 suggests that the logical inconsistency created by the change in P_B can be resolved in three ways: (a) by changing the intention to perform the behavior (P_I), (b) by changing the psychological relevance of the belief for the intention (i.e., by changing the difference $P_{I|B} - P_{I|\overline{B}}$), or (c) by a combination of the above. Which mode of resolution individuals use and the factors that influence this choice remain to be investigated.

Third, the model possesses obvious relevance to researchers in applied areas. On the basis of literature reviews or pretests, a set of beliefs may be generated for which measures in Equation 2 could be obtained. To understand variations in intentions, it would be possible to compare those who intend to perform the behavior with those who do not intend to on the strength of belief in each belief statement (P_{Bi}). A second comparison could be made between the two groups for differences in the psychological relevance of the belief for the intention (i.e., $P_{I|Bi} - P_{I|\overline{B}i}$). It is entirely possible that a given belief (P_{Bi}) will *not* covary with intention (i.e., that intenders and nonintenders will not differ on P_{Bi}), but that the belief will still be psychologically relevant to the intention (i.e., $P_{I|Bi} - P_{I|\overline{B}i}$ will be nonzero), and furthermore, that the magnitude of this relevance may differ as a function of whether or not the individuals intend or do not intend to perform the behavior. The present model allows the researcher to examine these factors for any number of groups defined on the basis of any "external" variable (such as sex or religion).

The present model of behavioral intention is based closely on Wyer's (1970) model of cognitive organization. It is not clear, however, whether research generated by Wyer and others in this area (e.g., McGuire, 1960a, 1960b, 1960c) is directly applicable to the present model. For example, it is not clear whether such phenomena as the Socratic effect and cognitive inertia would be observed when the criterion in question is a behavioral intention rather than a belief. The present data suggest that wishful thinking, for example, may *not* affect the behavioral intention model, although it has been shown to influence the cognitive organization model. Future research should help to identify the influence of these phenomena on beliefs versus behavioral intentions.

The present data do not allow a meaningful comparative test of the model of intention based on Equation 2 with other more prominent models (e.g., Fishbein, 1972: Triandis, 1974). Due to differing numbers of parameters, differing combinatorial rules, and differing reliability of measures, a prediction strategy such as the present one is simply not conducive to such comparative tests. However, the results of the present investigation are encouraging and suggest that comparative tests are worth pursuing. These would probably take the form of manipulative or change studies whereby differential predictions of the competing models are derived (e.g., one model predicts that a change in a belief should lead to a change in an intention, whereas another model does not).

Some additional advantages of the present model should be noted relative to other strategies for understanding the relationship between beliefs and behavior. One common approach used in relating beliefs to behavior is to obtain individuals' agreement or disagreement with a set of belief statements and then to correlate each one of these with behavior (in the present study, this would be analogous to correlating each P_B with the behavioral measure). These beliefs may be entered into a multiple regression equation and the overall multiple R as well as standardized regression coefficients of each belief interpreted. Alternatively, the belief ratings may be factor analyzed and the resulting factor scores entered into a regression equation. These correlational approaches suffer from two distinct shortcomings, however: (a) a belief may be highly correlated with a behavior yet still not have causal implications for the behavior (i.e., the correlation may be spurious) and (b) a belief may be uncorrelated with a behavior yet still have

causal implications for the behavior.[4] Any form of correlational analysis is ambiguous with respect to causality. In contrast, these problems are circumvented in the context of the conditional probabilities of the present model. If a belief is spuriously correlated with an intention (and hence, behavior), this should be reflected in a small difference between the conditionals $P_{I|B} - P_{I|\overline{B}}$. Similarly, if a belief is uncorrelated with an intention, yet has causal implications for it, this should be reflected in a large difference between the conditionals. Thus, the present model, if valid, circumvents some of the problems associated with these traditional correlational strategies.

A major difference between the present model and alternative approaches is the fact that most of these approaches explicitly consider multiple beliefs as determinants of intentions. Multiple belief measures are obtained and then combined in some fashion and related to the corresponding intention. This view is not incompatible with the present approach in that multiple beliefs are also considered. However, Equation 2 is applicable to only one belief at a time (i.e., measures of P_B, $P_{I|B}$, and $P_{I|\overline{B}}$ are obtained for each belief separately and analyzed accordingly). It would be possible to modify Equation 2 in accord with probability theory to incorporate multiple beliefs simultaneously. However, the equation would become cumbersome and would probably be of little practical utility when the number of beliefs is three or greater. The approach outlined in the present article is probably a more appropriate strategy. This approach should provide insights into the extent to which changes in any *one* belief will produce changes in behavior. It is possible that changes in one belief will not produce changes in behavior but that changes in multiple beliefs would. This state of affairs would be suggested by a set of beliefs whose psychological relevance $(P_{I|B} - P_{I|\overline{B}})$ was uniformly small.[5] In this situation, a model of multiple beliefs should be applied as a supplement to the present one. None of the current theories consider this problem, and such a model is now being developed and tested.

[4] An example will make this latter point explicit. A group of individuals may believe very strongly that a given airline is safe to fly on. Due to a restriction in range, a measure of this belief would not correlate with intention to fly on the airline. Nevertheless, if individuals learned that the airline was unsafe, this would probably have a decided impact on intentions.

[5] Alternatively, this might also suggest that each of the beliefs has nothing to do with the behavior.

Editors Named for New *Journal of Personality and Social Psychology*

The Publications and Communications Board has named Melvin Manis, Ivan D. Steiner, and Robert Hogan to edit the *Journal of Personality and Social Psychology* (JPSP), which will appear in a new format in January 1980. The affiliations of the new editors are, respectively, University of Michigan and Veteran's Hospital, Ann Arbor; University of Massachusetts; and Johns Hopkins University. Manis will edit the section on ATTITUDES AND SOCIAL COGNITION, Steiner the section on INTERPERSONAL RELATIONS AND GROUP PROCESSES, and Hogan the section on PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES.

An announcement on the restructuring of JPSP appeared on p. 668 of the June 1978 issue of JPSP. As indicated at that time, the three editors will work independently with separate groups of advisory editors. Their acceptances will appear as distinct sections in monthly issues of JPSP. Detailed descriptions of each section's coverage appear on pages 468–469 of the March issue of JPSP.

Authors should submit manuscripts to the appropriate section editor as follows:

ATTITUDES AND SOCIAL COGNITION

Melvin Manis
Research Center for Group Dynamics
Institute for Social Research
University of Michigan
Ann Arbor, Michigan 48106

INTERPERSONAL RELATIONS AND GROUP PROCESSES

Ivan D. Steiner
Department of Psychology
University of Massachusetts

NEW FOR 1980

ANNOUNCING!

PsycSCAN™ CLINICAL PSYCHOLOGY

PsycSCAN™ DEVELOPMENTAL PSYCHOLOGY

Two new abstract journals each with over 1,500 full abstracts per year from relevant, selected journals—APA and non-APA—in the fields of clinical and developmental psychology. These new publications are the results of more than three years of study and analysis of the information needs of APA members.

The unique scanning format of PsycSCAN allows the reader to quickly review the specially set title, index terms, abstract, and citation for each entry.

Keep current with the ongoing literature in these important fields in psychology. Plan to order one or both PsycSCAN journals when you complete your 1980 dues statement.

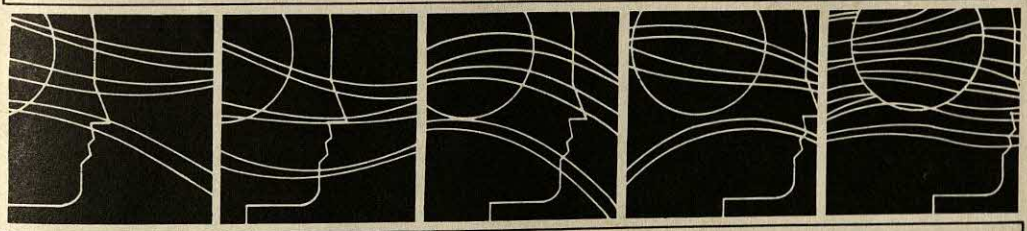
Each PsycSCAN journal is:

- $8 per year for APA members ($10 for nonmembers)
- Quarterly, starting in early 1980
- Available for easy check-off ordering on the 1980 dues statement

PsycSCAN™ is produced by PsycINFO™: a service of the American Psychological Association 1200 17th Street, NW Washington, DC 20036

Willo P. White, editor

Resources in Environment and Behavior



NEW FROM APA IN 1979

An invaluable sourcebook for students, instructors, and researchers in the new field of environment and behavior. This solid reference includes:

- Overview and history of this emerging field
- Graduate programs—both formal and informal
- Teaching innovations introduced in the United States, Canada, and Great Britain
- Funding sources
- Career opportunities
- Directory of key individuals currently working in the field
- Annotated bibliography
- Listing of relevant journals

Resources in Environment and Behavior is available from the American Psychological Association for $10 (soft cover only). To order, make your check payable to APA.

American Psychological Association
Order Department
1200 17th Street, NW
Washington, DC 20036

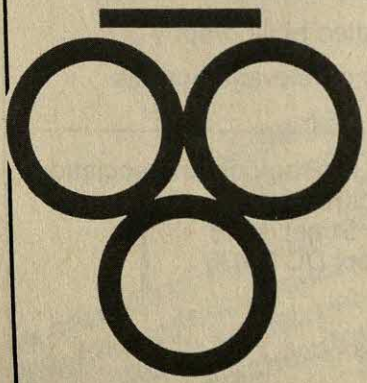
Please include full remittance for orders of $25 or less.

APA EMPLOYMENT BULLETIN

Possibly your key to greater career opportunities.

Each month 125 to 150 position openings are listed by geographical area and employment field for psychologists with a minimum of a Master's degree. Members may also publish availability notices. Coded identification numbers assure confidentiality. Ideal for employers, students, and Master's and Ph.D graduates.

A one year subscription is as little as $9.00 for members, $16.00 for non-members. If you're in a hurry, First Class delivery is available for an additional $4.00.



For more information, contact:
The Editor, Employment Bulletin,
or send your order to:

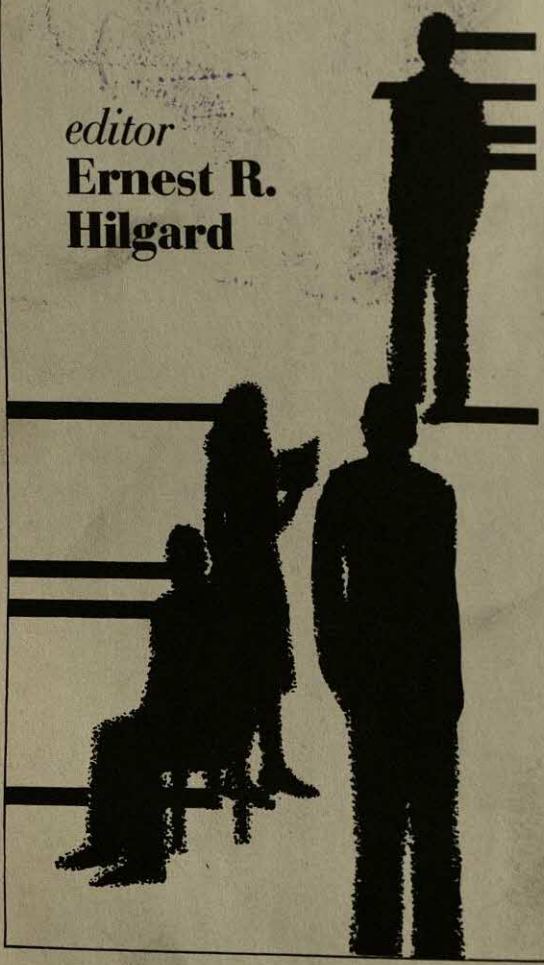
American Psychology in Historical Perspective

1892-1977

editor
Ernest R. Hilgard



Now available in one book — 21 APA presidential addresses in their entirety from some of the most important names in American psychology. Included are classic pieces from James, Cattell, Dewey, Thorndike, Woodworth, and Watson. You'll also find Harlow's "The Nature of Love" and Miller's "Analytical Studies of Drive and Reward."

This book is truly a milestone for historical psychology. It provides both a fascinating chronology of the presidents of the American Psychological Association from 1892 to 1977 and a valuable collection of significant essays.

This new APA publication traces the development of American psychology over four broad periods in psychology's history: the first 25 years (1892-1916), the years of the two world wars (1917-1945), the 20 years after World War II (1946-1967), and the recent past (1968-1977).

For each of these periods, the editor, Ernest R. Hilgard, provides a brief summary of the thinking in psychology at the time, biographies of all the APA presidents with abstracts of their presidential addresses, and the selected presidential addresses in full.

American Psychology in Historical Perspective *may be ordered in hard cover for $18 or in soft cover for $15 by writing to: American Psychological Association, Order Dept., 1200 Seventeenth Street, NW, Washington, D.C. 20036*

Please include full remittance for orders of $25 or less.

The Journal of Personality and Social Psychology publishes original reports of research, methodology, theory, criticism, and literature review in the fields of personality and social psychology of normal processes and populations. Submitted manuscripts should delineate an important question and provide a clear answer to it. In the case of research reports, this will often require demonstration that the reported results are generalizable beyond a single research setting. Consult the editorial in the January 1976 issue (Vol. 33, pp. 1–7) for a detailed statement of policies and instructions to authors.

Manuscripts: Submit manuscripts in quadruplicate, prepared according to the *Publication Manual of the American Psychological Association* (2nd ed.). Copies should be highly legible and will not be returned to authors unless they are original typewritten copies. Mail manuscripts according to instructions on p. 1439.

Required supplementary information: Manuscripts cannot be reviewed for publication unless the author provides supplementary information in the following categories: (a) a cover letter that indicates the relation (or the lack of relation) of the submitted manuscript to other papers by the same author(s) that are currently submitted, in press, or recently published; (b) one copy of each such related paper; (c) one copy of a statement of the procedures of the research reported in the submitted manuscript in sufficient detail to serve as a guide for conduct of an exact replication; and (d) one copy of the summary tables (e.g., correlation tables, analysis of variance summaries) for the *major* analyses reported. If it appears that the supplementary materials in categories (c) or (d) might be bulky, the author should exercise judgment and restraint in selecting what to send. It is not necessary to send supplementary material that repeats verbatim manuscript content.

After a manuscript is accepted, authors will be expected to provide assurance that their data are available in unanalyzed form for reanalyses by other investigators and that their research procedures were consistent with the American Psychological Association's published principles of research ethics, except insofar as may be detailed otherwise in the manuscript.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permission is normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of $10 per page, table, or figure. Abstracting is permitted with credit to the source. Permissions and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Permission and fees are waived for the photocopying of isolated articles for nonprofit classroom or library reserve use by instructors and educational institutions. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles with a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301. Address requests for reprint permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $60 domestic, $64 foreign, $6 single issue. APA member rate: $20. Write to Subscription Section, APA.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Published monthly in one volume per year by the American Psychological Association, Inc., 1400 North Uhle Street, Arlington, Virginia 22201. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

A Cybernetic Model of Self-Attention Processes

Charles S. Carver
University of Miami

An analysis of the experiential and behavioral consequences of self-directed attention is proposed, based on cybernetic or information-processing ideas. The proposed model includes the following assumptions: When attention is directed to environmental stimuli, those stimuli are analyzed and categorized according to the person's preexisting recognitory schemas. Self-directed attention often leads to a similar analysis of *self*-information; experientially, such a state of self-focus comprises an enhanced awareness of one's salient self-aspects. In some cases categorization—either of one's context or of some self-element—elicits a response schema, which constitutes a behavioral standard. If a prior categorization has evoked such a behavioral standard, subsequent self-attention engages an automatic sequence in which behavior is altered to conform more closely with the standard. This matching-to-standard is construed as the occurrence within a psychological system of a test-operate-test-exit unit or a negative feedback loop—a cybernetic construct applicable to many different phenomena both within and outside of psychology. More specifically, self-focus when a standard is salient is seen as the "test" or comparison phase of that feedback loop. If the matching-to-standard process is interrupted by one of several specified classes of events, subsequent behavior depends on an outcome expectancy judgment. A favorable outcome expectancy causes a return to the matching-to-standard attempt; an unfavorable expectancy results in behavioral withdrawal. Research support for the model is discussed, and comparisons are made with self-awareness theory, Bandura's theory of fear-based behavior, helplessness theory, and social comparison theory.

Psychological theorizing in this century has been characterized by the occasional emergence of quite general theories of behavior (such as psychoanalytic theory and learning theory), with intervening periods in which no general theory has seemed universally applicable and problem-specific theories instead have predominated. In recent years yet another general approach to understanding behavior has begun to coalesce, an approach usually identified with the terms *information-processing*, *cybernetic*, or *control* theory (e.g., Apter, 1970; Buckley, 1968; Powers, 1973; Singh, 1966; Wiener, 1948). In the minds of many theorists and researchers, information-processing ideas provide an ideal framework within which to confront a wide variety of problems. Indeed, it is a framework that, by virtue of its abstractness, many believe may provide the best basis yet attainable for a

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3708-1251$00.75

comprehensive model of behavior. This article represents an attempt to apply such ideas to an area of interest to social psychologists that has not been treated before in these terms. That area is the experiential and behavioral consequences of self-directed attention.

The article is divided into four major sections. The first section is intended to provide some background to the theory that is presented later. This background material includes a brief summary of Duval and Wicklund's (1972) theory of objective self-awareness and a basic introduction to the uses of the terms *cybernetic, control,* and *information processing*. In the second section a theoretical model is presented, along with some evidence in support of its propositions. This section represents the central portion of the article. Because of the unique relationship between this theory and Duval and Wicklund's (1972) self-awareness theory, a third section is included, which addresses specific points of conflict between the two models. The present theory also has some broader implications, however. These implications are considered in the final major section. That section includes comparisons between the present model and each of the following: Bandura's recent analysis of fear-based behavior (Bandura, 1977), learned helplessness theory (e.g., Abramson, Seligman, & Teasdale, 1978), and social comparison theory (Festinger, 1950, 1954).

Background

Self-Awareness Theory

In 1972 Duval and Wicklund proposed a theory of self-awareness that consisted of two central assumptions. First, they suggested that the objects of conscious attention could be dichotomized: Attention can be directed outward to the environment, or attention can be directed inward to the self (self-awareness).[1] Self-awareness is increased by stimuli that remind a person of himself or herself (e.g., a camera or a mirror); self-awareness is decreased by stimuli that distract attention from the self (e.g., perceptual-motor tasks, such as a pursuit rotor).

Duval and Wicklund's (1972) second assumption was that self-focus leads to a self-critical evaluation process such that the self-attentive person compares himself or herself with some standard on whatever behavioral dimension happens to be salient (see also Wicklund, 1975a).[2] Those authors further argued that self-directed attention is therefore usually aversive, because in most cases the person's actual behavior or state is worse

My most sincere gratitude is expressed to Clyde Hendrick, Hazel Markus, Paul Neumann, John Rosen, Michael Scheier, Neil Schneiderman, Shelley Taylor, Robert Wicklund, and particularly Paul Blaney, all of whom generously commented on one or more drafts of this article; to Mark Bickhard, who gave me my introduction to the concepts of cybernetics; and to my wife, Nora de la Garza, who remained unfailingly supportive throughout the long and arduous process of shaping the manuscript.

Requests for reprints should be addressed to Charles S. Carver, Department of Psychology, P.O. Box 248185, University of Miami, Coral Gables, Florida 33124.

[1] Duval and Wicklund (1972) originally termed self-focus "objective" self-awareness and environment focus "subjective" self-awareness. In recent years this rather cumbersome convention has been widely abandoned in favor of such alternatives as high versus low self-awareness or self-focus versus environment focus.

[2] It will be noted that many *potential* standards of comparison exist at any given moment, even with respect to a single behavioral dimension. However, in Duval and Wicklund's theory it was assumed that at any given time the following two conditions obtain: One standard is more salient than others, and the person *adopts* that standard as his or her comparison value, at least temporarily. The same assumption will be made throughout the present discussion. Cases in which the individual's attention is drawn to a potential standard that is not adopted as a comparison value (because it is seen as irrelevant to one's behavior or for some other reason) are explicitly excluded from the analysis. This issue will be taken up in somewhat greater detail below.

Perhaps the distinction between standards and dimensions should also be clarified at this point. The distinction is similar to that commonly made between the terms *value* and *variable*. A behavioral dimension (or a variable) such as aggressiveness or politeness is defined by some quality that may be present in one's behavior to a greater or lesser degree. A standard is a point on that behavioral dimension, for example, nonaggressiveness or moderate aggressiveness. The existence of a behavioral standard, of course, always presupposes the existence of a behavioral dimension.

than the standard of comparison. This aversiveness presumably leads the person to attempt to escape the self-aware state (Wicklund, 1975a, 1975b). If it is not possible to avoid self-awareness-inducing stimuli (and thus the aversive state), the self-focused person may attempt to alter his or her behavior so that it conforms more closely to the standard, as a way of reducing the aversiveness of self-awareness. That is, the aversiveness of self-attention was seen as the motivator for behavioral alterations. Thus self-awareness theory, as proposed by Duval and Wicklund (1972), was one of a larger class of drive theories—one in which the presence or absence of drive was determined by the direction of one's focus of attention.

This theory has been provocative, and it has led to a good deal of imaginative research. However, evidence has begun to accumulate that its assumptions are incorrect. The remainder of this article will be devoted to the assertion that the elements of self-awareness theory that have been supported by research findings can be most usefully construed as components of a more elaborate model of social cognition, and further, that such a model is most usefully framed in information-processing or cybernetic terms.

Information Processing, Cybernetics, and Control

Definitions. Some amplification on the uses of the terms *information processing, cybernetic,* and *control* is in order at the outset. The term *information processing* is used in two related but distinguishable ways by psychologists. At a micro level, the term refers to analyses of the exact bases by which information is encoded in and retrieved from memory. At the macro level, *information processing* applies to descriptions of control systems and is more synonymous with the term *cybernetic.* Cybernetics is the science of control and communications systems (Apter, 1970; Singh, 1966; Wiener, 1948, 1954). The term *control,* as used here, refers to the sequencing that is implicit in a set of instructions, each of which awaits and depends on the execution of the previous instruction (as in a computer program).

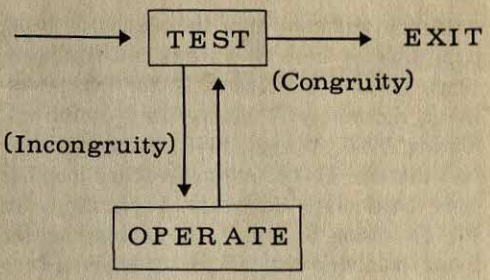

Figure 1. The TOTE unit, as presented and discussed by Miller, Galanter, and Pribram (1960).

A specific illustration may clarify the concept of control. Miller, Galanter, and Pribram (1960) introduced to psychologists a hypothetical construct called a TOTE unit (Figure 1); the word TOTE is an acronym for test-operate-test-exit. This construct is known more widely among cyberneticists and engineers as a negative feedback loop (negative because it reduces discrepancies between an existing state and a standard).

The diagram of a TOTE unit (Figure 1) portrays a self-regulatory system. The arrows in the diagram convey three things simultaneously. They represent energy, that is, the activation of a physical mechanism to do some sort of work; they represent information transfer, that is, the information that congruity between two values has or has not been attained; and they represent control, the fact that one process logically depends on an outcome of the previous process and then leads to a subsequent process. Any given process is said to control another when the execution of the first triggers the execution of the second. In effect, any decision-making flow chart describes a control sequence.

In general, the present use of the term *information processing* is meant to convey the latter (macro-level) meaning of the term. Though there are differences in implication between the terms *information-processing, cybernetic,* and *control* theory, the differences are relatively subtle, and the terms will be used interchangeably here.

Applications. Many people tend to think of the word *cybernetic* as applying solely to electronic computers. However, cybernetics as

a science was seen from its infancy as being applicable to both living and nonliving systems. To most cyberneticists, the living–nonliving dichotomy is not terribly useful (cf. Turing, 1950; Wiener, 1948). Because of the fact that the TOTE unit or feedback loop has some particularly important implications for the discussion to follow, let us consider the living–nonliving distinction as it applies to the TOTE unit (Figure 1).

In the control system of the TOTE unit, three mechanisms are activated in an orderly sequence. The first of these—*test*—is a mechanism by which a comparison is made between some input and a standard. If the input is not congruous with the standard, the second mechanism—*operate*—is activated. *Operate* alters the existing state of affairs in some way. Following *operate, test* recurs. If the input now is congruous with the standard, the final mechanism—*exit*—occurs, deactivating the system or freeing it for other applications. If, on the other hand, the second *test* reveals that incongruity still exists, *operate* is reactivated and continues to sequence alternately with *test* until congruity between input and standard is attained [3]

The most commonly used illustration of the operation of a TOTE unit is the behavior of a nonliving system: the room thermostat. The thermostat senses existing temperature, compares that existing temperature with a preset standard, and activates a furnace when the temperature falls discriminably below the standard or activates an air conditioner when the temperature rises above the standard. However, this control structure is certainly not limited to electrical systems. Indeed, in the view of cyberneticists, the feedback loop may occur in virtually any type of physical system (cf. Buckley, 1968; Kuhn, 1974). The same control structure that is realized electrically in the thermostat is realized biologically in innumerable forms: for example, the homeostatic mechanisms that maintain normal body temperature, maintain appropriate levels of oxygen and nutrients in the blood and tissues, and regulate hormonal balances (cf. Wiener, 1948, especially p. 114). Moreover, the same control structure can be realized in psychological systems. For example, it is implicit in a child's self-correcting attempts t reach out to touch a nearby object, and in th adult's checking and adjusting his or he clothing in a mirror.

Until recently, cybernetic constructs hav not been widely applied to subjects of interes to social psychologists. The theorizing pre sented below is intended, in part, as a ste in that direction.[4]

The Model

The control-theory model of self-attention processes proposed here subsumes many findings generated by researchers in self-awareness theory. It does not, however, incorporate all of the same assumptions as does that theory. The difference in assumptions between the two allows the present model to accommodate existing data with greater internal consistency and to make predictions that seem not to be easily derivable from self-awareness theory as framed by Duval and Wicklund (1972). The model consists of the following propositions, which will be presented along with some amplification and supporting evidence. (Figures 2 and 3 provide a flow-chart illustration of the interrelationship among propositions.)

1. *A dichotomy may be imposed on the potential objects of conscious attention, such*

---

[3] This alternation may be quite rapid, of course, depending on the characteristics of the physical system in which it occurs. (Indeed, some theorists, e.g., Powers, 1973, hold that this information flow is better conceptualized as being continuous at all stages of the feedback loop.) Thus, although we can easily separate the component elements logically, for other purposes it is more convenient to think of the entire feedback loop as the unit of analysis.

[4] Control theorists seem to have been more aware of the potential applications of such constructs to social behavior than have social psychologists. For example, MacKay (1963) has noted that "an artifact capable of receiving and acting on information about the state of its own body can begin to parallel many of the modes of activity we associate with self-consciousness" (p. 227). An important exception to this general rule is the work of Powers (1973, 1978), whose background includes training in both psychology and physics. Even Powers's writing, however, has been concerned predominantly with psychological processes other than those involved in social behavior.

that attention may be said to be directed either outward toward the environment or inward toward the self.

This seemingly simple statement (which is identical to the first assumption made by Duval and Wicklund, 1972) requires several kinds of qualification and elaboration. First, it should be clear that the dichotomy between self-focus and environment focus is an imperfect one (as in some respects is the distinction between what is self and what is nonself). When one's attention is focused on the environment, one is attending to immediate perceptual input from the distance receptors: the eyes and ears. Self-focus, in comparison, includes a wider variety of possibilities. When attention is self-directed, it sometimes takes the form of focus on internal perceptual events, that is, information from those sensory receptors that react to changes in bodily activity (for example, the autonomic and proprioceptive activity that contributes to the subjective experience of emotion). Self-focus may also take the form of an enhanced awareness of one's present or past physical behavior, that is, a heightened cognizance of what one is doing or what one is like. Alternatively, self-attention can be an awareness of the more or less permanently encoded bits of information that comprise, for example, one's attitudes. It can even be an enhanced awareness of temporarily encoded bits of information that have been gleaned from previous focus on the environment; subjectively, this would be experienced as a recollection or impression of that previous event.

It is sometimes difficult to maintain the clarity of this dichotomy, as is illustrated by the following example. To look at a part of one's own body is, initially, to focus on the environment. The visual perception is a perception of a thing out in the world, until that percept is categorized as an aspect of self. Because the visual stimulus in question is a part of one's body, however, it is likely that it will ultimately be categorized as a component of self. At that point the experience may become one of self-attention, as one mentally considers that self-aspect. It is this mechanism by which experimental manipulations such as mirrors presumably act to heighten self-focus: by inducing visual perceptions that remind subjects of themselves in a very general sense, that is, remind them of self-dimensions other than their visual representations.

It should also be clear that the term *heightened self-awareness* and its synonyms as they are used in this article do not necessarily connote a long, deep examination of the self. Rather, such terms imply an increase in the probability or the frequency with which attention is momentarily directed to some aspect of the self. In research, such increases in self-focus are caused by stimuli that remind subjects of themselves. It is assumed, however, that attention normally shifts back and forth between self and environment to some degree, whether such reminders are present or not.

2. *When attention is directed to the environment, incoming stimulus information is processed, leading to classification of that input.* The process of classifying incoming stimuli has been studied extensively by cognitive psychologists. Posner (1969; see also Posner & Rogers, 1978), Franks and Bransford (1971), Reitman and Bower (1973), and Neumann (1974) are among the theorists who have developed models to account for the classificatory process in various ways. Though these models vary in other respects, they have as a unifying idea the notion that, over a succession of perceptual experiences, a single representation in memory is abstracted from a series of relatively similar percepts. This single representation, then, stands for a class of perceptual events. These abstracted representations—sometimes termed *recognitory schemas* or *recognitory prototypes*—are stored in memory and are subsequently used to classify and interpret new inputs.

Evidence for the existence and use of recognitory prototypes in classifying stimuli in the environment comes from a vast accumulation of research in cognitive psychology. In cognitive research, the prototypes are typically generated experimentally by presenting subjects with a series of discrete training stimuli that vary along several dimensions. After training, subjects are found to classify new stimuli according to the organization implicit in the training series. Presumably the catego-

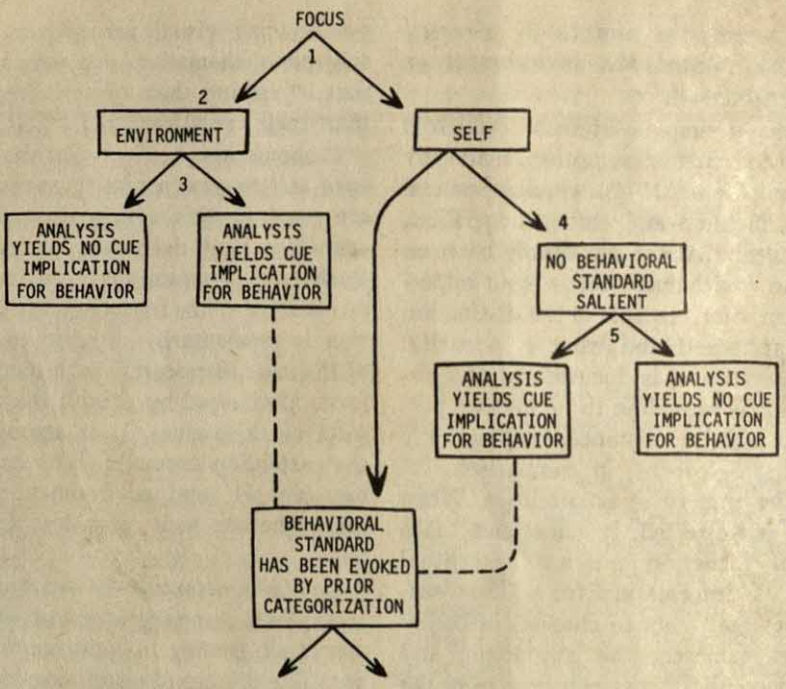

Figure 2. Flow-chart description of the cybernetic model of the consequences of self-directed attention. (Numbers in the figure refer to comparable propositions in the text.)

rizational structures that we carry with us in our day-to-day lives similarly reflect our experiential histories, but histories that are much longer and more complex.[5]

In the restricted settings of cognitive research, the subject categorizes only one stimulus at a time. However, in the broader context of social behavior one doubtless categorizes the nature of the interaction setting as a whole, as well as categorizing single stimuli. The kinds of information contributing to this overall identification undoubtedly include gestural, postural, and other nonverbal cues emitted by persons in the visual field; significant physical elements in the situation (e.g., presence of objects with identifiable uses); and verbally transmitted information, including inferences that the listener makes from the verbalization. Each cue that is encoded presumably contributes something to the resultant categorization of the context.

The work of a number of environmental psychologists (e.g., Barker, 1968; Fredericksen, 1974; Gump, 1971) would seem to fit very easily into this line of thought. Those researchers have emphasized that behavior settings vary along many discriminable dimensions, and they have worked toward the development of taxonomies of the situations in which behaviors take place. Presumably their efforts in categorization are similar to the processes that we all use continuously, albeit less consciously. In a similar vein, Cantor and Mischel (1977) have recently found evidence that personality-trait terms act very much as recognitory prototypes in the classification of other persons.

The classification of environmental inputs, which is assumed in the present model to

[5] The specific processes by which such schemas are formed and altered, although obviously very important, are outside the scope of this article. Thus, the experimental literature of that area is treated quite peripherally here. Inasmuch as this article is intended to deal primarily with consequences of self-directed attention, discussion will emphasize research with direct relevance to the propositions that deal with self-focus.

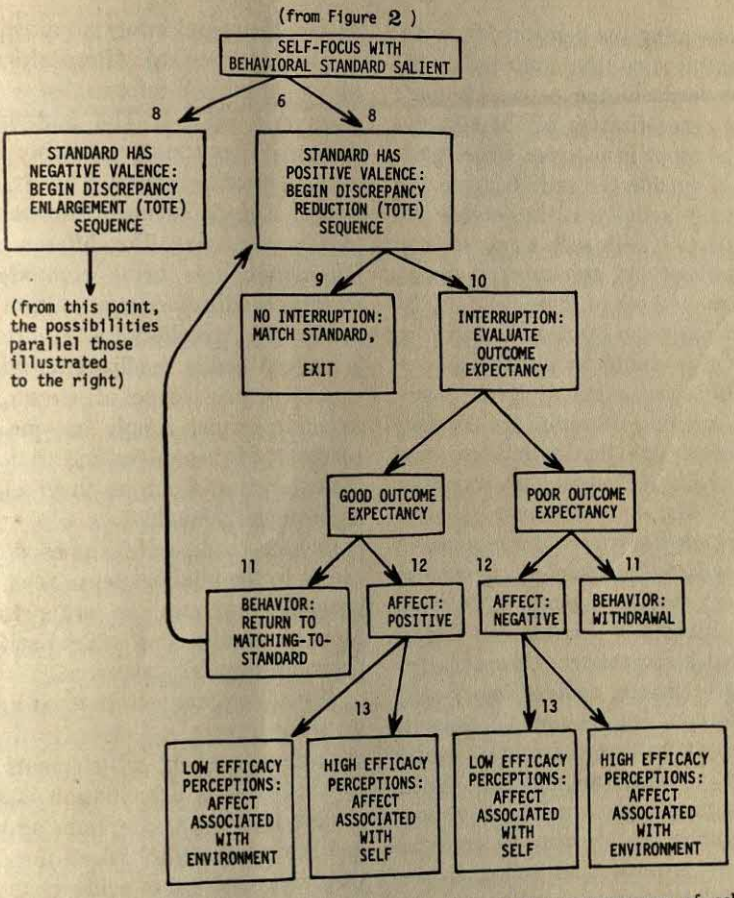

Figure 3. Flow-chart description of the cybernetic model of the consequences of self-directed attention. (Numbers in the figure refer to comparable propositions in the text.)

occur whenever attention is directed outward to the environment, is presumed to be an interactive process. That is, it involves a comparison of the incoming information with preexisting recognitory schemas.[6] Indeed, many believe that the resulting percept is as much a function of the previously encoded information as it is a function of the input information itself (cf. Neisser, 1976). The fact that this categorization involves such an interaction between input and schema suggests another qualification that must be made regarding the proposed dichotomy between self-focus and environment focus. Specifically, if processing and classification of even a very simple sensory input occurs by reference to preexisting recognitory prototypes, it would appear to be an oversimplification to say that attention is ever directed "at" the environment alone. The prototypes are, in a very basic sense, an aspect of oneself. The processing of environmental information thus seems to involve the simultaneous utilization of an aspect of the self.

At our level of analysis, however, the dichotomy still remains useful and meaningful. When internally stored schemas are accessed for comparison with environmental input during normal perception, this accessing occurs preattentively. It is the resulting percept that is represented in consciousness, not the evoking of the schemas. With regard to conscious experience, then, it seems quite reasonable for us simply to ignore the role played by the

[6] The perceptive reader may have noted that this activity in itself represents a TOTE unit at a lower level of analysis than is being emphasized in this paper.

schemas in generating the percept. Moreover, it bears repeating that the function of the sequence that leads to the percept is quite obviously the categorization of the stimulus input—and the input is an event whose point of initiation is outside the self. Because this is the goal of the activity, it thus seems reasonable to refer to it with such terms as *focus on the environment* and *processing* of *incoming information*. In both of these respects, the proposed dichotomy can be viewed as a verbal shorthand that is useful in classifying conscious experience at a macro level (where most of our present concerns are located) even while recognizing that at a micro level much more complicated events are occurring.

3. *In some cases, response-prototype information either constitutes part of a recognitory prototype or is directly implied by the recognitory prototype; in other cases, this information is not contained or implied* (see Figure 2). Saying that a recognitory schema used to identify one's behavioral context does specify response-prototype information is exactly equivalent to saying that the context evokes in the person a behavioral standard. As an example, most people in our culture have been taught to dampen the intensity of their behavior—that is, to speak and walk quietly—in places that are classified as religious in nature. When a person with this behavioral schema classifies a behavioral setting as being religious, quietness is immediately evoked as a behavioral standard.

Recognitory schemas do not always contain this kind of response-specifying information, however. In social psychological terms, many situations exist in which no particular standard of appropriate behavior is salient, where guidelines for action are not implicit in one's recognition of the nature of the context. Whether a situation has or has not evoked a response prototype as a behavioral standard has important implications for what occurs when attention is self-directed.

4. *If a behavioral standard has not already been evoked by classification of one's context, attention directed to the self leads to increased awareness of salient self-elements* (Figure 2). Stated another way, the analysis and categorization that were postulated above to occur for environmental information when attention is directed outward (Proposition 2) occur with regard to self-information when attention is directed inward. The underlying components of this process presumably are the same as those discussed above. That is, comparisons are being made between information and recognitory schemas. The difference is that the information now being compared with the schemas is self-information—information from within (e.g., recollections of prior behaviors or present bodily feedback activity). Experientially, in this type of circumstance, self-attentive persons simply become increasingly cognizant of themselves and their own salient characteristics, much as they might examine any external stimulus.

In such cases, self-focus is not evaluative except in the minimal sense that preattentive analysis "evaluates" in order to categorize. More specifically, this state of self-focus is not phenomenologically aversive.

The notion that self-directed attention may in some cases lead simply to heightened awareness of salient self-elements rather than to a self-*critical* examination is a major departure from the assumptions on which Duval and Wicklund (1972) based their theory. Yet there is a good deal of evidence to support this assertion. This evidence will be reviewed in the following paragraphs.

Duval and Wicklund (1973) themselves demonstrated that more self-attentive subjects make greater self-attributions for hypothetically experienced outcomes than do less self-attentive subjects. This outcome has since been replicated (Buss & Scheier, 1976), although other research suggests some limitations on the effect (Hull & Levy, 1979). It may be that the mere heightened salience of self as an entity led subjects in the Duval and Wicklund (1973) and Buss and Scheier (1976) studies to weight the self more heavily in the judgments they made. Alternatively, perhaps the salient aspect of self in this attribution-making context is one's potential as a causal agent (cf. Duval & Wicklund, 1973).

The reasoning that salient self-aspects may be more fully represented in consciousness when self-focus is high than when it is low has also been extended to the internal experi-

ence of emotional states (Scheier & Carver, 1977). In that research, it was proposed that when one's attention is self-focused in a context in which there is affect, one may attend to that affect as being the salient component of self. Thus, in two of Scheier and Carver's studies, subjects who had experienced positive and negative mood inductions subsequently reported feeling more elation and depression, respectively, when more self-attentive than when less so. In two additional studies, subjects reported experiencing greater attraction and repulsion toward pleasant and unpleasant slides, respectively, when self-attentive than when not. Others (Borkovec & O'Brien, 1977) have found similarly that directing a subject's attention to his or her bodily responses leads to an increase in the self-reported intensity of the emotion being experienced.

The notion that heightened self-focus leads to enhanced awareness of one's internal state suggests another interesting possibility: that self-focus can lead to heightened awareness of the *absence* of anticipated internal activity. This hypothesis was recently tested (Gibbons, Carver, Scheier, & Hormuth, 1979), in a study in which some subjects were led to expect arousal symptoms from a pill, whereas others were not. In all cases the pill was a placebo. Among subjects who expected arousal, fewer symptoms subsequently were reported by self-focused subjects than by those with less self-focus.

The Gibbons et al. (1979) finding appears to indicate that when led to expect a different internal state than is actually present, the self-attentive person has greater access to the veridical internal state than does the less self-attentive person. Two additional studies (Scheier, Carver, & Gibbons, in press-a) have investigated further this heightened awareness of internal experience among self-attentive persons by assessing whether it can serve to reduce other kinds of suggestibility phenomena. In the first of these studies, subjects were exposed to stimuli of moderate sexual attractiveness, which they were instructed to evaluate on the basis of their own bodily reactions. Subjects were led, however, to anticipate either highly arousing or very nonarousing stimuli. Subjects with experimentally heightened self-attention were less misled by these cues than were subjects in whom self-focus had not been increased. The second study extended the reasoning to the experience of taste. Subjects were led to expect either an increase or a decrease in a flavor intensity (relative to a previous sample); they then received either a slightly stronger or a slightly weaker solution. The intensity judgments subsequently made by highly self-attentive subjects were less in line with manipulated anticipations and more in line with actual flavor intensities than were judgments made by less self-attentive subjects. Thus, again, self-focus minimized suggestibility, apparently by increasing awareness of an actual internal experience.

Nor is the increased accuracy of self-report that occurs under high self-focus limited to reports of internal perceptual experiences. Other studies (Pryor, Gibbons, Wicklund, Fazio, & Hood, 1977; Scheier, Buss, & Buss, 1978) indicate that self-focus enhances people's accuracy in reporting on their habitual behavioral tendencies. Thus, for example, self-reports of sociability that were made under conditions of heightened self-attention were found to be highly correlated with unobtrusive measures of actual social behavior; reports made by less self-attentive subjects, on the other hand, poorly represented their actual behavior (Pryor et al., 1977). Presumably, self-attention provides more veridical or more thorough access to the memories that are relevant to such self-reports. Additional evidence that self-focus increases the activation of self-relevant memory areas has been provided by Geller and Shaver (1976).[7]

---

[7] In addition to determining ease of access to previously stored information, the direction of one's attention probably also has implications for the access one has to schemas for use in encoding new stimuli (whether they be self-stimuli or environmental stimuli). Thus, for example, when one is self-focused, one may not have good access to the schemas that are typically used for encoding information about the environment (cf. Vallacher, 1978). Indeed, easy access to a schema may increase its use, even in situations where such use would not otherwise be expected. This may be the mechanism behind the "top of the head" phenomena discussed by Taylor and Fiske (1978), in which some particularly salient

A final illustration of the fact that self-attention can lead simply to greater cognizance of the self comes from research conducted by Carver and Scheier (1978) as validation of self-awareness manipulations. Subjects in that research completed a self-focus sentence completion blank (Exner, 1973) developed and validated earlier as a measure of egocentrism. This instrument was completed either in an empty room or in the presence of a self-awareness-inducing stimulus. As was expected, proportionally more self-focus sentence completions were emitted in conditions of heightened self-awareness than under control conditions.

Salience. One final issue, implicit in much of the above discussion, probably should be addressed at this point. What determines which aspect of the self is "salient" when attention is self-directed and which aspect of the environment is salient when attention is directed to the environment? A full and complete answer to this question cannot yet be given. Doubtlessly the ultimate answer will be complex. However, one determinant of salience probably derives directly from the interactive nature of the categorization process described above. As was noted, classification of the environment takes place by comparison of input against recognitory prototypes. If the prototypes to which the environmental inputs correspond have cue implications for some specific self-information, the self-information is probably accessed (in a preliminary preattentive fashion) by the very process of classifying the environmental input. The aspect of self that is represented by that self-information presumably will be more salient than other self-aspects when attention is subsequently directed inward. Another way of saying this is that when we attend to the self, we are often examining an aspect of self that has been suggested by some cue in our environmental context. For example, an environmental stimulus that is categorized as *typically emotion-inducing* may cue a search for bodily arousal as a salient self-dimension when attention is self-directed. Indeed, such a cue implication may serve in vivo as an impetus to shift focus from the environment to the self.

Similarly, the self-aspect that has just been under examination may be a major determinant of the aspect of the environment that is salient when attention is directed outward. For example, consider a case in which self-attention has had as its object an existing state of bodily arousal for which there is no recognized antecedent. In such a case, it seems likely that attention subsequently directed outward would be oriented specifically to searching for aspects of the environment that are categorizable as potentially arousing. Thus a self-aspect can have a cue implication for some aspect of the environment, leading to heightened salience of that aspect when one's focus turns outward. More simply, when we attend to the environment, we are often focusing on aspects of the environment that have been suggested by some cue within ourselves.

5. *Just as categorization of environmental stimuli sometimes evokes a behavioral prototype as a standard, a categorization of a salient self-aspect may in some cases evoke a behavioral standard* (see Figure 2). As an example, a salient emotion might evoke a prototypic response *to* that emotion. The research presented above regarding awareness of affect was limited to reports of subjective emotional experiences. Other research has demonstrated, however, that heightened awareness of an affect may also lead to increased behavioral responsivity to the affect. For example, Scheier (1976) found that provoked aggression was more intense among more self-focused than among less self-focused subjects.[8] Other research (Scheier, Carver,

stimulus exerts an inordinate influence on subjects' behavior. This notion might also have some relevance to the recent finding that imagining an event increases the degree to which a person expects the event to occur (Carroll, 1978).

[8] Scheier (1976) found that subjects' personal attitudes toward aggression did not correspond to the aggression they actually emitted. However, an attitude is only one type of standard that is potentially applicable in that context. The issue of varieties of standards will be addressed more fully below. The position taken here with regard to the Scheier (1976) data is that awareness of anger evoked a stereotypic retaliatory response prototype and that the prototype was used as a comparison value for subsequent behavior.

Schulz, Glass, & Katz, 1978) has demonstrated that feelings of sympathy are expressed to a greater degree among more self-attentive than among less self-attentive persons. Finally, yet other studies (Scheier, Carver, & Gibbons, in press-b) have shown that strong fear leads to greater avoidance among more self-attentive than among less self-attentive persons.

6. *A standard can have either a positive or a negative valence.* A positive valence implies that the standard is taken as a "desired" goal state. A negative valence exists when a standard of comparison is taken as an "undesired" goal state. Valences presumably are based on previous learning and generalization and on temporary encoding through imitation and verbal transmission. Multiple or component valences can easily exist with respect to any specific standard, of course. Consider, for example, the teacher's behavioral standard of going from the office to teach a class. On a given day the teacher may feel that he or she should go to the class because teaching is his or her vocation (positive valence); the teacher may also feel like not going because the teacher does not enjoy the class (negative valence). One important component valence, of course, occurs as a function of an obligation to do the behavior in question (cf. Vickers, 1973).

It seems likely that any given component valence can also vary in salience over time. Its salience is likely to depend on the salience of the environmental cues to which the valence is attached. For example, if bright, interested students have just been in the teacher's office, a positive valence may be salient. Presumably the accumulation of these component valences (weighted by salience) determines the overall valence of the standard as discussed here.

7. *Standards and behavioral dimensions can also vary in importance.* There are at least two ways in which importance may be construed in informational terms. The first depends on association of positive or negative events with the stimulus class during the person's prior experiences. A *priority label* may become part of the categorization as a function of the intensities of such events. High intensity events (e.g., strong punishment for poor behavior with respect to a standard) would lead to a high priority tag or "importance"; low intensity events would lead to a tag of less priority.

A second possibility concerns the centrality or interrelatedness of a behavioral dimension with respect to other dimensions. Importance in this case would be defined according to the number of cross-reference tags attached to a given behavioral dimension that refer to other behavioral dimensions. For example, the amount of work that one person does may be weighed in his or her mind as important, but its importance does not extend to other areas of the person's life. The work, in effect, is left at the office. In contrast, another person may not only see his or her work output as important but may also view it as having implications for other parts of his or her life, for example, interpersonal relationships. The work output dimension thus would be effectively more important for the second person than for the first, by virtue of its interconnectedness with other dimensions.[9]

8. *If a behavioral standard has been evoked either by environmental input or by a salient self-element, subsequent self-focus leads to a comparison between self (one's present behavior or characteristics) and the previously evoked standard. Comparison between self and a positively valenced standard leads to discrepancy reduction; comparison between self and a negatively valenced standard leads to discrepancy enlargement* (see Figure 3). The comparison between self and standard is regarded as representing the test phase of a psychological TOTE unit. It thus leads to the engagement of one or the other of two possible adjustment and feedback sequences: either a negative feedback loop (discrepancy reduction) or a positive feedback loop (discrepancy enlargement).

The notion that heightened self-focus leads

[9] Standards can also vary in their degree of acceptedness, which is logically distinguishable from importance, even though the two in reality are often confounded. A standard that one accepts half-heartedly will be less reflected in behavior than one accepted enthusiastically.

to increased conformity of one's behavior to a salient standard was, of course, a main tenet of self-awareness theory, although for quite a different reason than is assumed here. Self-awareness theory held that discrepancy reduction was one of several potential responses to the postulated aversiveness of self-attention. The present model assumes that the discrepancy-reduction impulse is affect free and is the prepotent response to the recognition of a discrepancy. These distinctions are important ones and will be elaborated more fully in a later section of the paper.

Discrepancy reduction. Whatever its basis, the prediction that self-directed attention leads to heightened conformity to the salient behavioral standard has received ample research support. For example, a series of studies of instrumental aggression showed that subjects matched their behavior to salient standards (which varied from study to study) to a greater degree when made more self-aware than when less self-aware. In the first of these studies (Scheier, Fenigstein, & Buss, 1974), self-focus caused male subjects to conform to a "chivalry" norm when shocking a female victim who had not provoked them. In a second study (Carver, 1974), female subjects shocked at higher levels when self-focus was increased, in line with an experimentally induced standard in which high shock was portrayed as desirable. In yet other studies (Carver, 1975), subjects' aggressive behavior was more consistent with their previously verbalized attitudes when the subjects were more self-attentive than when less so.

Moreover, demonstrations of the fact that self-focus leads to increased conformity to standards are by no means limited to studies of aggression. For example, in an experiment in which speed of copying prose was made salient as a standard of comparison (Wicklund & Duval, 1971), more prose was copied within a given time span by subjects in whom self-focus was heightened than by those in whom it was not. In addition, compared to less self-aware controls, self-aware subjects have been found to behave more consistently with their previously assessed stage of moral reasoning (Froming, in press) and more consistently with their previously assessed levels of sex guilt (Gibbons, 1978).

Discrepancy enlargement. The notion that standards can have negative valuation and that focus on those standards leads to discrepancy enlargement has received much less attention than has the matching-to-standard process. However, this notion is logically consistent with an older idea in social psychology. Newcomb (1958) wrote of the "negative reference group," a group with which one does not identify, but with which one actively compares oneself. Such a comparison allows one to emphasize, and indeed to further increase, the existing differences. Newcomb coined the term negative reference group in the context of social comparison theory (Festinger, 1950, 1954). Yet the nature of the process that Newcomb proposed is strikingly similar to the process proposed above for cases in which some negatively valenced behavioral standard is salient. The difference is that in the present model the comparison value need not be the attitudes or behavior of a particular group of people. It can be any negatively valenced value that is taken up for purposes of comparison. (The relationship between the present theorizing and social comparison theory will be examined in more detail in a later section of the article.)

Another class of behavior that can be viewed as discrepancy enlargement is a phenomenon that is usually analyzed in terms of psychological reactance (Brehm, 1966; Wicklund, 1974). Researchers have demonstrated repeatedly that coercive attempts to persuade lead to resistance to persuasion or even to attitude change in a direction opposite to the position being advocated (e.g., Brehm & Brehm, 1966; Snyder & Wicklund, 1976). Such effects may be interpreted as attempts to distance oneself from the standard of comparison (i.e., the position that is advocated in the communication). In the present model that standard would acquire a negative valence in very much the same manner as was postulated by Brehm (1966)—that is, by virtue of the threatening elements contained in the associated communication. Consistent with the reasoning that distancing-from-standard might occur under these circumstances

in response to self-focus, Carver (1977) has found that attitude reversal in response to a coercive communication was greater among self-focused subjects than among less self-focused subjects. Similar results have occurred in two additional studies (Carver & Scheier, in press).

Standards. Standards for self-comparison can vary widely, both in terms of their specific nature and in terms of their source. One reasonable distinction in this regard would be between the *type* of a standard and its *content*. For example, smoking in response to stress is different in content from eating, or pacing in response to stress. Yet they are all similar in one respect: They are of the type called *habit*. A personal-preference attitude is a different type of standard. A third type is an attitude based on more complex reasoning, for example, moral reasoning. Similarly, an instruction from another person that is adopted and conformed to is different in type from all these, as is the temporarily assumed socially desirable behavior that others nearby are exhibiting. With these multiple possibilities of source, type, and content, what determines which is evoked in a given situation and is thus taken as the comparison value when one is self-focused?

Specific applications of this general question abound in personality and social psychology. For example, the literature of moral development is replete with illustrations of the fact that moral reasoning is a judgmental *capability* rather than a typical way of behaving. Under which conditions will a person respond to a moral choice by exerting his or her psychological capabilities to their fullest, and under which conditions will the person's behavior be dictated by other considerations? The answer to this question is by no means clear, for the following reason. Although categorization processes and the use of categorizational schemas to classify and interpret information have recently begun to receive attention from social psychologists (e.g., Cantor & Mischel, 1977; Kuiper & Rogers, 1979; Markus, 1977; Rogers, Kuiper, & Kirker, 1977; Rogers, Rogers, & Kuiper, 1979), thus far virtually no work has been aimed explicitly at understanding the process of extracting behavioral prototypes in response to environmental cues. Which standard becomes salient in a given experimental situation has usually been more a matter of good intuitions on the part of the researcher who is preparing the situation than a matter of precise analysis of the determinants of salience. Quite obviously, this entire question is an important area for future work. For the present, let us simply note that matching-to-standard effects appear to have been demonstrated with regard to all of the following: habits[10] (Liebling, Seiler, & Shaver, 1974), personal-preference attitudes (Carver, 1975), moral reasoning capabilities (Froming, in press), and experimentally provided instructions (Carver, 1974).

9. *Matching-to-standard is the normal consequence of self-attention when a behavioral standard is salient, until and unless the process is impeded in some way.* (Although this and the following propositions will be framed in terms of matching-to-standard, it should be clear that the same logic is applicable to distancing-from-standard phenomena; see also Figure 3). Throughout a discrepancy-reduction sequence, self-focus represents a recurrence of the *test* mechanism of the psychological TOTE unit. *Test* will continue to alternate with one or more *operate* mechanisms until behavior or present state is brought into line with the standard. As in any TOTE se-

---

[10] The fact that matching-to-standard apparently can occur with regard to habits as standards raises the additional question of how "conscious" the process is in such cases. Matching to a habit standard may feel very unconscious, phenomenologically, for the following reason. The degree to which execution of a behavioral sequence seems conscious depends on the salience of its component acts and their consequences; this in turn depends on the degree to which those acts are monitored while being carried out. In habitual activity, the behavioral components have previously been encoded as a well-connected chain (cf. Schank & Abelson, 1977, discussion of cognitive "scripts"). To use TOTE terminology, a single *operate* consists of a behavioral sequence rather than a small bit of behavior change. Therefore, fewer tests are required over the course of the behavior than is the case for other, less well-known behavioral sequences. The relative paucity of attention devoted to monitoring this behavior suggests that it may be experienced less completely in consciousness.

quence, if successful completion of matching-to-standard occurs, it is followed by disengagement.

This proposition stands in direct contradiction to the assumption in recent statements of self-awareness theory (Wicklund, 1975a, 1975b) that the prepotent response to self-focus in a standard-salient context is avoidance of self-awareness rather than discrepancy reduction. As was noted above, this contradiction has important ramifications that will be considered further in a later section of the paper.

10. *If something impedes the matching-to-standard process, behavior is interrupted and an assessment process is evoked* (see Figure 3). This assessment entails the further processing of relevant information, yielding an outcome expectancy: an estimate of the likelihood of being able to more closely approximate the standard, based on the nature of the situation and on the behaviors available to the person. This assessment process can occur prior to the initiation of behavior if, for example, the person has foreknowledge that the behavior is going to be difficult to execute successfully. Alternatively, it can occur during the matching-to-standard sequence if the person encounters difficulty in either selecting or executing the appropriate operation to move toward the standard.

The assessment of outcome expectancy may be an evaluation of the likelihood of attaining the overall goal, given the context and one's resources. Alternatively, if the matching-to-standard sequence involves separable steps, it may be an assessment of the likelihood of attaining the next step. In either case, the assessment process has two products: One is behavioral, the other affective. These will be considered in turn.[11]

11(a). *If the assessment process leads to a favorable outcome expectancy, the behavioral response is a return to the matching-to-standard sequence* (Figure 3).

11(b). *If examination of the context and one's resources reveals a low subjective probability of being able to alter behavior appropriately, the behavioral consequence is withdrawal.* The latter would appear to represent a disengagement from the dimension in question, a kind of going-out-of-the-field phenomenon (cf. Lewin, 1935). In practice, this could take the form of a mental dissociation from the dimension (refusal to consider further) or could occur as a behavioral withdrawal from contextual elements that either heighten self-attention or make the standard salient.

There are several types of events that can potentially prevent or disrupt the matching-to-standard process. One possibility is that the behavior in question is fixed in the past. If there is no opportunity available to repeat, reattempt, or undo the behavior, it is thus rendered unchangeable. In such a case, discrepancy reduction cannot even begin. An example of this state of affairs occurred in a study conducted by Duval, Wicklund, and Fine (1972). Some subjects in that study were informed that their scores on a previously administered test of intelligence and creativity were very discrepant from the levels that they had anticipated and desired. Moreover, it was implicit that the test was not going to be repeated, nor was any other opportunity to be provided for reducing the discrepancy (thus all subjects would have had low outcome expectancies with regard to matching the behavior to standard). In this study, subjects who were to wait for another experimenter after receiving the negative feedback withdrew sooner if the room contained a self-attention-heightening stimulus than if it did not.

Results of a more recent study (Steenbarger & Aderman, in press) confirm that this withdrawal tendency depended on the fact that the behavioral discrepancy was portrayed as unalterable. This study made use of a paradigm derived from that of Duval et al. (1972), but one in which there was ostensibly to be a second task. Steenbarger and Aderman (in press) found that when subjects experi-

[11] This proposition and the two following propositions, though derived independently, have a good deal in common with Stotland's (1969) analysis of *hope* as a psychological construct. Stotland used the term *hope* to refer to the perception of a high probability of attaining a goal and the term *anxiety* to refer to the perception of low probability of attaining a goal.

enced an inflexible discrepancy—that is, when the impression was created that subjects could not expect to alter their performances appreciably—self-awareness hastened withdrawal. When the impression had been created that improvement was a real possibility, on the other hand, no increase in withdrawal occurred as a function of self-attention.

Intrapersonal deficit. A second set of conditions that may lead to behavioral interruption stems from the possibility that the execution of the behavior in question requires specific skills, abilities, or characteristics that the person is not certain he or she possesses. The implication that these skills are required may cause the discrepancy-reduction attempt to be suspended and cue the assessment process. An example of the importance of this possibility is provided by recent studies of fear-based behavior conducted by Carver and Blaney (1977a, Experiment 3; 1977b). In those studies, some subjects were chosen explicitly on the basis of their doubts about their ability to cope with fear, whereas others were chosen as believing that they could cope with their fear. All of these subjects, however, reported having identical (moderate) degrees of fear. It seems reasonable that signs of fear while attempting to approach and pick up the feared stimulus (in this case, a snake) should cue a self-assessment process in all such subjects. In the Carver and Blaney (1977b) study, the subjects who doubted their abilities to overcome their fear (i.e., who had chronically low outcome expectancies) reacted to the perception of rising fear, induced via false heartbeat feedback, by avoiding attending to the behavior–goal comparison (according to self-reports) and by withdrawing behaviorally. The latter effect replicated a previous finding (Carver & Blaney, 1977a, Experiment 3). In contrast, those subjects who had expressed more confidence about being able to go through with the behavior (i.e., who had chronically higher outcome expectancies) responded to the perception of anxiety by focusing *more* on the behavior–goal comparison and attempting—successfully—to match the one with the other.

The Carver and Blaney (1977a, 1977b) studies investigated the behavioral consequences of variations in expectancy, but those studies did not explicitly incorporate experimental manipulations of self-focus. More recently, however, a similar study has been conducted using a conventional self-awareness manipulation (Carver, Blaney, & Scheier, 1979). In that experiment, confident subjects were found to be undeterred by heightened self-awareness during the approach task, but doubtful subjects withdrew earlier in the approach sequence when self-focus was high than when it was lower. Postexperimental self-reports formed a pattern that was consistent with the present model, that is, that heightened self-attention had led to increased awareness of fear among *all* subjects and thus to self-assessment during the approach sequence; that self-assessment, in turn, had led to continued approach attempts among confident subjects and to early withdrawal among doubtful subjects.

This result has recently been conceptually replicated (Carver, Blaney, & Scheier, in press) in quite a different behavioral domain: i.e., responses to failure. All subjects in that research were confronted with a failure experience on an intellectual task, in order to create a large self-versus-standard discrepancy. Subjects then undertook a second task, ostensibly bearing on the same intellectual skill. Rather than assessing subjects' chronic expectancies, however, as had been the case in the Carver et al. (1979) study, an experimental manipulation of outcome expectancy was introduced. Subjects were led to believe either that they could potentially do quite well on the second task, or that they would probably do quite poorly. In reality, the second task was a measure of persistence. As predicted, subjects in whom unfavorable expectancies had been induced were less persistent when self-focus was high than when it was low. Also as predicted, subjects with favorable expectancies were more persistent when self-focus was high than when it was low.

The tasks in all of the above research provided subjects with escapable situations. That is, it was possible for subjects engaged in task attempts in those studies to withdraw physically from the behavioral context. This pos-

sibility does not always exist, however, when a perceived self-deficiency threatens one's behavioral adequacy. For example, consider the person with severe test anxiety who must take an unavoidable test. While in the testing situation, such persons probably are very susceptible to being interrupted from their performance attempts by stimuli that cue outcome assessment. In many test situations, this assessment yields unfavorable expectancy judgments. Because they cannot withdraw behaviorally, however, these persons may be frozen in the self-assessment phase of the sequence, where they repeatedly reconfront the evidence of their own inadequacy. Attempts at task-relevant activity are sporadic because outcome assessment indicates that such attempts will be unsuccessful, and the attempts are short-lived because the assessment process is likely to be re-evoked. Thus the test-anxious person is caught in a cognitive loop in which self-assessment and cognitive disengagement from the task predominate, rather than renewed effort.

This portrayal is consistent with Wine's (1971) characterization of the test-anxious person as being chronically self-focused in situations where the adaptive response is to be task focused. The present model seems more adequate than is Wine's, however, in two respects. Though Wine's analysis would not necessarily predict that self-focus can facilitate performance among persons low in test anxiety, the present model clearly does. Such performance facilitation has been demonstrated elsewhere (Wicklund & Duval, 1971). The present model also implies that self-focus can facilitate performance even among highly test-anxious persons, if circumstances lead those persons to have positive outcome expectancies. This possibility does not seem derivable from Wine's (1971) theory. Recent research (Slapion & Carver, Note 1) has yielded evidence that this can occur as well.

Environmental constraints. Yet a third set of conditions that would lead to behavioral interruption is the possibility that some feature of the environment may prevent the successful execution of the appropriate behavior (a circumstance that fits the usual operational definition of frustration). To use a somewhat trivial example, if one goes shopping at a time when stores are closed, one typically withdraws from the attempt. This withdrawal does not occur, however, until one's attempt has been interrupted and the realization has occurred that the desired outcome is unlikely (i.e., low outcome probability). The notion that environmental constraints lead either to withdrawal or to attempts to circumvent them seems a very obvious point. This case is discussed here largely in order to point out that the psychological processes implicit in this class of events are the same as those that occur in the other event classes discussed above. This indicates the high degree of generality of the processes under consideration.

Novelty. The analysis presented here of processes leading to withdrawal also bears some resemblance to Berlyne's (1963) discussion of the somewhat perplexing fact that novelty sometimes leads to approach, sometimes to withdrawal. He proposed that the presence of some degree of "collative" (i.e., comparison-requiring) properties in a stimulus (novelty, for example) engages exploration, movement toward the stimulus in order to assimilate it. Too much of the same properties, however, leads to withdrawal. According to Berlyne, the reason for this withdrawal is that the organism assesses the alterations required to assimilate the stimulus as being beyond its present capabilities. In effect, outcome expectancy with regard to assimilation is negative, and withdrawal is the consequence.

12(a). *The judgment that one cannot alter one's behavior in the direction appropriate to the standard may also lead to negative affect in proportion to the importance of the behavioral dimension or the standard and the perceived magnitude of the discrepancy.*[12] This negative affect remains present as long as the person focuses on the judgment that he

[12] It seems worth reemphasizing that importance here refers to importance as defined by oneself. A standard that others view as important but that seems irrelevant to oneself is for present purposes *not* an important standard.

or she cannot reduce the discrepancy. Evidence for this proposition comes from a study (Steenbarger & Aderman, in press) that was discussed above in connection with the assumption that self-focus leads to withdrawal only when discrepancy reduction is prevented in some way. That same study also showed that subjects who had been led to believe that they could not reduce the discrepancy experienced more negative affect when self-focus was high than when it was lower. This effect did not occur among subjects who expected to be able to reduce the discrepancy.

12(b). *Engagement of the assessment process can also lead to positive affect, if assessment leads to the perception of a favorable outcome probability.* This is comparable to Simonov's (1970) argument that emotion becomes positive when "there is a surplus of information available as compared with the information necessary to satisfy a sufficiently strong need" (p. 147). This is the elation experienced, for example, when one knows that one knows *how* to arrive at the solution of a problem, even though the problem has not yet been solved.[13]

The assumption of two potential responses (behavioral and affective) to the assessment of outcome expectancy raises a question as to their relationship. The two may be parallel responses. For example, both the cessation of behavioral attempts and the experience of negative affect may be cued by a recognition that nothing can be done to improve one's present state. This would be similar in some respects to Leventhal's (1970) parallel response model of reactions to fear communications. An alternative possibility is that behavioral withdrawal may occur as a response to the existence of negative affect. It is not possible to specify the relationship unequivocally at this time. It seems clear, however, that environmental constraints on potential behavior will have a large role in determining which of the two response modes predominates, particularly in cases of unfavorable outcome expectancy. That is, when the environment permits withdrawal, withdrawal should predominate. When the environment does not permit withdrawal, negative affect should predominate.

13. *Affect that results from assessment of outcome expectancy can take one of two forms, depending on the cognitions associated with the affect* (see Figure 3). What cognitions are linked to negative affect will be determined by the person's perception of the locus of the barrier to behavior alteration. If the person has a low *efficacy* expectancy—that is, if he or she perceives that behavior is being impeded by a self-deficit—the affect will be associated with the self. It may be reflected in such ways as reduced self-esteem. If the person has high efficacy expectancy and perceives that his or her behavior is impeded by some environmental constraint, the affect will be associated with those constraining elements. It may be reflected by such things as expressions of resentment.[14] Similarly, what cognitions are associated with positive affect will be determined by the perceived locus of the cause of favorable outcome expectancy. The affect will be associated with the self if personal efficacy is seen as having caused the good outcome to be likely; it will be associated with the environment if the positive outcome expectancy is ascribed to a benign environment. Although the logic behind this proposition is relatively straightforward, these predictions remain to be tested.

Comparisons With Self-Awareness Theory

At least three questions deserve further consideration with regard to differences between the present model and self-awareness theory as proposed by Duval and Wicklund (1972)

---

[13] This analysis may help to account for the observation that the anticipation of a pleasant event often seems more pleasurable than the event itself, as if knowing that the outcome will occur is better than its occurrence. Indeed, this would be consistent with the frequently expressed observation among psychologists that "the fun is over" once an idea has been conceived and a study to test it is designed.

[14] It may be this variable that distinguishes, for example, between depression attributed by a client to environmental contingencies and depression attributed to inadequacies of the self. That is, insufficiently positive outcome expectancies lead to depressed affect, but whether cognitions of self or environment are associated with the negative affect may vary with efficacy expectancies.

and amended by Wicklund (1975a). They are the following: (a) Under what conditions is self-attention aversive? (b) What instigates or energizes the matching-to-standard process? (c) Finally, what is the prepotent response to self-focus when a behavioral standard is salient—discrepancy reduction or withdrawal? These issues will be discussed in the following three sections.

Aversiveness of Self-Focus

One important area of conflict between the present model and that of Duval and Wicklund concerns whether negative affect is an inevitable consequence of self-attention, and if not, what other conditions are necessary for it to occur. Duval and Wicklund (1972) and Wicklund (1975a, 1975b) have argued that any time a discrepancy exists such that one's present state or behavior is worse than the standard of comparison, self-attention is aversive.[15] "It is assumed that the objectively self-aware person will not simply react to himself impartially and in a neutral manner, but that he will come to evaluate himself as soon as the objective state occurs" (Duval & Wicklund, 1972, p. 3). "Certainly objective self-awareness is postulated to be an aversive, motivational state" (Wicklund, 1975b, p. 80). Indeed, as was stated at the beginning of the present article, the postulated aversiveness of self-attention was that theory's crux. In contrast, it has been proposed here that self-directed attention leads to negative affect only when the person perceives that he or she cannot alter his or her present state in the direction of the standard. (This discussion will be framed in terms of discrepancy reduction, but it is of course applicable to discrepancy enlargement as well.)

It is instructive to note that the studies cited as evidence of the unpleasantness of self-focus were invariably cases in which a within-subjects discrepancy existed *and in which subjects were prevented from altering their present state or behavior*. For example, in the first demonstration that subjects would attempt to escape from self-focus (Duval et al., 1972), the subject's behavior on the relevant dimension was anchored in the past and thus could not be altered in the direction of the standard. Similarly, though self-esteem has been found to be reduced when subjects were made self-aware (Ickes, Wicklund, & Ferris, 1973), it is unclear to what degree that finding depended on the nature of the study's dependent measure. The dependent measure was a comparison between subjects' self-rated real selves and ideal selves along several dimensions. Subjects in that research had no way to *alter* their real selves. They were simply reminded of the real–ideal discrepancy to a greater degree when self-awareness was heightened than when it was not.

Aside from these examples in which subjects' behavior or characteristics were unchangeable, there appears to be no evidence that self-attention itself is phenomenologically aversive. To the contrary, Steenbarger and Aderman (in press) found an increase in negative affect only when self-focus was combined with a nonreducible discrepancy; when the discrepancy was flexible, the opposite tendency occurred. Similarly, Carver and Scheier (1978), in demonstrating that the presence of either a mirror or an audience increases self-focus, were unable to find any evidence that self-attention led to negative affect. A similar conclusion has also been reached by other researchers (Davis & Brock, 1975; Hull & Levy, 1979).

Affect and valuation. There is only one restricted sense in which the present model implies the existence of something resembling negative affect whenever self-attention is directed to a behavior–standard comparison. It may be useful in this regard to draw a distinction between the phenomenological experience of affect and the function of valuation (cf. Diggory, 1966, p. 70). The event that initiates the matching-to-standard sequence according to the present model is the fact that the *test* of the TOTE unit assesses

[15] Wicklund (1975a) has also pointed out that the existence of a positive discrepancy (i.e., self better than the standard) is a different case, leading in his view to positive affect. The present discussion, however, will be limited to instances of negative discrepancy, as has implicitly been the case throughout the article.

the existence of a discrepancy between a present state and an accepted goal state. Inasmuch as the function of the behavior change (*operate*) is to reduce the discrepancy, it is possible to construe the recognition of the discrepancy as being (on some level) a negatively evaluated event. However, there seems to be no reason to assume a concomitant phenomenological experience of negative emotion. As was noted in the preceding paragraphs, however, there is substantial reason to believe that negative affect occurs in cases when one is prevented from reducing those discrepancies (Duval et al., 1972; Steenbarger & Aderman, in press). Thus the data seem consistent with the assumption in the present model that self-focus has phenomenologically affective consequences only following outcome assessment.

To the degree that negative affect is experienced in contexts in which behavior change is (objectively) not difficult, it may be seen as a variation of the inability-to-alter experience. For example, a workman who repeatedly reaches to the wrong spot for tools may feel negative affect, not because of failure to reach the tool, but because the inability to correct the initial reaching impulse is beginning to alter his perceptions of self-efficacy with regard to tool handling. Similarly, a man at a formal dinner who suddenly realizes that he has been eating his salad with the wrong fork can easily alter his behavior. Any negative affect he experiences is caused by concern that his behavior may be regarded by others as uncultured and the possibility that he will not be able to alter the first impression that he has thus created. Finally, the perception of the need for a discrepancy reduction that will take an extraordinarily long time can lead to negative affect. However, this should occur only if there are salient doubts as to the ultimate outcome. If there is a positive outcome expectancy—*hope,* in Stotland's (1969) terms —positive affect should ensue, even if many months of behavior remain between the person and his or her goal.

Instigation of Matching-to-Standard

There is a second important distinction between the present model and Duval and Wicklund's (1972) theory that is intimately bound to the question of whether self-focus is aversive. This second distinction concerns the question of how behavior change is instigated and energized when self-focus occurs and a behavioral standard is salient. As was mentioned above, Duval and Wicklund (1972) devised their model from a drive-theory perspective. By postulating that self-focus is aversive any time a within-self discrepancy exists, those authors could assume that subsequent behavior change was energized by a drive state and was instigated by that drive state's aversiveness.

In the present model, in contrast, the matching-to-standard sequence that is engaged when self-focus occurs in the presence of a salient behavioral standard is seen as the realization within a psychological system of a negative feedback loop. The fact that self-attention is required in order to engage the matching-to-standard sequence is interpreted in control-theory terms in the following way. Self-focus in a standard-salient context represents the *test* phase of the TOTE unit: an assessment of whether a discrepancy exists. The behavioral response to self-focus (the alteration of behavior in the direction of the standard) is the *operate* phase. The ordering of the control sequence of the feedback loop dictates that *operate* cannot take place before *test* reveals a discrepancy. Thus, focus on a discrepancy is required to engage the TOTE sequence. In phenomenological terms, this awareness simply corresponds to the realization that one is *in* a context in which there is a standard to match with one's behavior. A change in behavior depends on that realization.

Inasmuch as both models assume a comparison process between self and standard, the critical difference between them in this context seems to be the presence or absence of a drive postulate. This issue introduces considerable theoretical complexity, stemming from two facts: first, that a great many variants of drive as a construct have been proposed over the years, and second, that there is far from universal agreement on what measurable state, if any, corresponds to a theoretical state of heightened drive. A completely

adequate treatment of this complexity is well beyond the scope of the present article. The interested reader is referred to Appley's (1970) review article for a more detailed critique of drive and arousal constructs. Consideration of the issues here will be much more limited.

Does self-attention heighten drive, or does it not? One might at first view this as an empirical question, although it will be argued below that this appearance may be illusory. However, let us consider the existing evidence on the relationship between self-focus and drive. Although agreement on the nature of drive is often difficult to obtain, as was noted above, many researchers have assumed that drive is either equivalent to, or reflected by, autonomic arousal.[16] To the limited degree that evidence on this point is available, self-attention appears not to lead to an increase in physiological arousal. If one were willing to equate such arousal increases with heightened drive, it would thus appear that self-focus is not drive inducing. Evidence on this issue comes from two sources.

Salience of nonarousal. One set of data comes from a study (Gibbons et al., 1979) that was discussed earlier as evidence that self-attention when no standard is salient merely makes one more conscious of one's salient characteristics. Subjects in that study were led to anticipate that arousal symptoms would occur as a function of a pill (actually a placebo). Subjects later reported the extent of their symptoms, with self-attention heightened or not. If self-directed attention per se were arousal inducing, greater arousal should have been experienced, and thus reported, by subjects in the high self-awareness condition than by control subjects. Instead, the opposite occurred. Self-attentive subjects apparently became more conscious of the *absence* of arousal (consistent with the present informational analysis) and consequently reported fewer symptoms.

One difficulty with applying this finding to the drive question, however, is the fact that in the early statement of their theory, Duval and Wicklund (1972) largely ignored the possibility that a standard of comparison might not always be present. Wicklund (1975a) later concluded that self-focus was aversive only if one's present state was worse than a salient standard of comparison. However, he argued at the same time that one was almost always worse than some standard and that one would ultimately become conscious of that discrepancy. Nevertheless, if self-attention should be drive inducing only when a discrepancy exists between self and standard, and if it were possible to assume a case within Duval and Wicklund's framework in which no standard is salient, then those authors might thus anticipate that self-focus would not increase drive in the Gibbons et al. (1979) case.

Physiological data. A second set of data on the arousal question does exist, however (Paulus, Annis, & Risner, 1978). Moreover, this finding is not liable to the caveat that was applied above to the Gibbons et al. finding. Paulus et al. gave subjects a task (copying prose) with a clear standard (copying quickly). As subjects prepared to attempt the task, either before a self-focusing stimulus or with no such stimulus present, the experimenter took a physiological measure called the palmar sweat index (Johnson & Dabbs, 1967). Increased palmar sweat values have commonly been believed to reflect increased arousal (cf. Geen & Gange, 1977; Martens, 1969a, 1969b). However, in the Paulus et al. study, *lower* values on this index were found among more self-aware than among less self-aware subjects. The meaning of the palmar sweat index is open to considerable question on other grounds (see the following paragraphs). But if that measure were acceptable as an index of drive, the finding of Paulus et al. would seem to contradict Duval and Wicklund's assumption that self-attention is drive increasing.[17]

---

[16] Though it certainly oversimplifies the case to imply that all theories utilizing a drive construct contain this assumption, it is probably fair to say that it is implicit in the large majority of drive models in social psychology.

[17] The data of Paulus et al. were derived in the context of a social facilitation paradigm. The present theoretical model has rather extensive implications for social facilitation phenomena, although consideration of those implications is beyond the scope of this article. These implications are, how-

It was noted above that the arousal or drive issue is not entirely an empirical one. There are also two important logical considerations that render the entire arousal controversy somewhat less meaningful.

The meaning of physiological indices. First, contemporary researchers in physiological psychology tend to recoil at the mere suggestion that autonomic arousal is a unitary phenomenon. Such psychologists are inclined to look at autonomic indicants in terms of what specific functions they imply rather than whether the organism is aroused. For example, Sokolov (1963) has proposed that one pattern of physiological responses comprises an "orienting" response, whereas another pattern comprises a "defensive" response. The orienting response is held to facilitate greater knowledge of an external stimulus by making the organism more receptive to input information from that stimulus. The defensive response, in contrast, involves an inhibition of sensitivity to input information (cf. also Hare & Blevings, 1975). This latter function presumably protects the organism from overstimulation.

This argument is easily taken one step farther, by assuming that such function-specific physiological response patterning is a normal concomitant of different kinds of *consciously controlled* behavioral involvement. Williams, Bittker, Buchsbaum, and Wynne (1975) have discussed this possibility in some detail (see also Lacey, 1967). They reasoned that experimental tasks vary in the types of attentional demands they make (as opposed to the degree of demand). Some tasks (e.g., a visual decoding task) require sensory intake; others (e.g., mental arithmetic) require sensory rejection. Conceptually, the sensory intake pattern seems similar to Sokolov's (1963) orienting response; the sensory rejection pattern, though not particularly "defensive," seems to embody many functional components of Sokolov's defensive reaction, in that there is a suppression of sensory input. In the Williams et al. analysis, however, this pattern simply reflects the attempt to concentrate focus inward and prevent distraction. In a test of this reasoning, Williams et al. (1975) were able to show that subjects differed as predicted in cardiovascular response patterns as a function of the type of task being performed.

It is instructive to note, in this regard, that initial theorizing about the palmar sweat index (Dabbs, Johnson, & Leventhal, 1968) concerned attentional issues fully as much as it concerned arousal. Dabbs et al. (1968) argued that increased palmar sweat was associated with readiness to engage the environment, and that decreased values reflected self-directed attention and an attempt to concentrate. These descriptions seem a good deal like the sensory intake and sensory rejection patterns of Williams et al. (1975). Taken together, these two descriptions converge on two notions, one of them general and the other more specific. The general one is that at least some physiological indices may be more usefully construed as providing information about attentional and information-processing phenomena than as providing information about arousal. The more specific one is this: that the finding of decreased palmar sweat in the presence of a self-attention-inducing stimulus (Paulus et al., 1978) may most reasonably be interpreted in attentional terms, as reflecting inward focus of attention and the simultaneous suppression of environmental input.

Cybernetics and the energizing of behavior. In addition to constraints imposed by the complexity of the meaning of autonomic responses, another issue of logic should be addressed. This issue concerns the nature of cybernetic theory.

Among persons accustomed to think of behavior as being "energized" and thus impelled by some kind of drive, the idea that a control-theory model of motivation is truly adequate to explain variations in the intensity of behavior will seem difficult to accept. This is true even though a number of motivational psychologists (e.g., Guilford, 1965; Hunt, 1965; Taylor, 1960; Vickers, 1973) have for a number of years characterized the TOTE

---

ever, taken up elsewhere (Carver & Scheier, Note 2). That paper also presents further data on the role of drive in social facilitation and self-awareness phenomena.

unit as the most promising model of motives leading to intentional activity.

The sticking point for many people seems to be the obvious fact that it takes energy to do work. Thus a drive model would seem to be preferable to a control-theory or a cybernetic one. But this view fails to recognize the fact that physiological changes that occur in the course of executing a behavior are in no way incompatible with cybernetic assumptions. Cybernetic theory would simply relegate the observed physiological change to a secondary causal role. As Guilford (1965) has noted, "In automated devices, as in living organisms, there is a clear distinction between two functions of energy. There is the energy that carries out the various operations, where work must be done, and there is the energy that has control functions, where triggering and release of much greater quantities of energy are involved" (p. 320). Cyberneticists would tend to emphasize the importance of the energy that has control functions, even though it is the work-doing energy that is most readily observed in terms of changes in physiological state. Thus Wiener argued long ago (1948) that the then-current focus on arousal was misguided, that the body is in fact very far from being a conservative system with limited energy available. He argued that the appropriate type of "bookkeeping" for events in the nervous system is not one that is energy based. Instead, the critical notions were those of message, quantity of information, coding technique, and so on.

It should be repeated, however, that the fact that physical work systems are subsidiary components of the body's control system has this important implication: Covariation of physiological change with behavioral change in no way constitutes a threat to a control-theory analysis of behavior regulation. In such an analysis, a change in physiological activity leads merely to the question of what specific functions are being performed, rather than the more misleading question of whether arousal exists. Indeed, for this reason it is arguable (see also Carver & Scheier, Note 2) that control theory provides a more subtle understanding of physiological events than does drive theory.

Prepotent Response Tendency

There is a third distinction between the Duval and Wicklund (1972) model and the present model that should also be addressed. It bears on the following question. In a context in which a behavioral standard is salient, which response is prepotent when self-focus occurs: matching-to-standard or withdrawal? In the model proposed here, the matching-to-standard sequence is prepotent, as part of the human being's normal self-regulatory system. Withdrawal occurs only after an outcome assessment and only if that assessment yields a negative expectancy. In contrast, although Duval and Wicklund (1972) originally felt that it was not possible to know which of these two modes would be preferred, Wicklund later argued for an ordering opposite to that assumed in the present model. "Certainly a successful averting of self-focused attention would eliminate the negative affect, however temporarily; thus an individual's immediate reaction to objective self-awareness should be an avoidance of self-focusing stimuli and/or efforts to find distractions" (Wicklund, 1975a, p. 236). Thus, according to Wicklund, discrepancy reduction occurs only when self-focus cannot be avoided.

Results of two recent studies (Carver, Blaney, & Scheier, in press; McDonald, in press) suggest that the present analysis is the more accurate of the two. In McDonald's research, subjects in whom a large negative within-self discrepancy had been made salient were more persistent on a subsequent task (for which persistence had been defined as appropriate) when self-focus was increased than when it was not. Moreover, there was also evidence that this effect was exaggerated by instructions that the second task was relevant to the dimension on which the discrepancy had been created. The possibility that subjects had simply been distracting themselves from self-focus by burying themselves in their task was considered and rejected by McDonald, because of the fact that a much simpler and quicker means of avoiding self-focus was readily available but was not used, that is, announcing "I'm finished" and leaving the context. Thus McDonald con-

cluded that discrepancy reduction is prepotent under self-focus when a means of reducing the discrepancy is available.

The Carver et al. (in press) research was discussed earlier in this article, in the section on outcome expectancy. Some subjects in that research were led to have favorable expectancies of being able to reduce a large within-self discrepancy, others were led to have unfavorable expectancies. Subjects with favorable expectancies were more persistent when self-attention was high than when it was low, consistent with the McDonald (in press) results. Carver et al. rejected the possibility that this persistence represented attempted distraction for the same reason as had McDonald, that is, that there was an easier way to avoid self-focus readily available. Indeed, this point is further emphasized in the Carver et al. research by the fact that one group of subjects *did* utilize that way of avoiding self-focus—specifically, subjects with negative outcome expectancies. Thus those results appear to be unequivocal in supporting the present theory.

Other Theoretical Comparisons

The model proposed in this article also bears certain similarities to models in social psychology other than self-awareness theory. Three of the similarities are striking enough that they deserve some separate attention. The first of these concerns Bandura's recent (1977) analysis of fear-based avoidance behavior; the second concerns recent analyses of human helplessness (Abramson et al., 1978; Wortman & Brehm, 1975); the third concerns social comparison theory (Festinger, 1950, 1954). These similarities will be discussed in the following sections.

Self-Efficacy and Avoidance

The fact that the approach–withdrawal decision process postulated here has been framed in terms of outcome and efficacy expectancies suggests that some commonality may exist between the present model and Bandura's recent analysis of the role of self-efficacy expectancies in avoidance behavior (Bandura, 1977; Bandura, Adams, & Beyer, 1977). Bandura's analysis and the present one do share some common ground, but they also differ in important respects.

Terminology. The first difference is one of terminology (see Figure 4). Bandura used the term *outcome expectancy* to refer to "a person's estimate that a given behavior will lead to certain outcomes" (Bandura, 1977, p. 193). His primary concern was in distinguishing that belief from the expectancy that one can *execute* the behavior. This he labeled *efficacy expectancy*. Clinically, such a distinction is quite an important one. In many cases people know what behavior a situation requires but do not believe themselves capable of doing the behavior. Because efficacy expectancy was most clinically relevant and thus most important to Bandura, he devoted relatively little attention to defining and discussing outcome expectancy. Implicitly, however, outcome expectancy in Bandura's terms is based only on the presence or absence of knowledge about the normal consequences of a behavior. In the present model, in contrast, the term outcome expectancy is used to denote expectancy about an event's likelihood of occurrence. This usage quite explicitly includes a variety of inputs: knowledge of the normal consequences of task-appropriate behavior, constraints imposed by external forces or by the passage of time, and efficacy expectancy—one's judgment about whether or not one can execute the requisite behavior (Figure 4).

In the present model, therefore, outcome expectancy is the direct determinant of the person's subsequent behavior and affect (Propositions 11 and 12). Efficacy expectancy is merely one input into outcome expectancy, but one determining what cognitions are associated with affect experienced as a function of that outcome expectancy. In Bandura's model, in contrast, the person's efficacy judgment is the direct determinant of his or her subsequent behavior. Outcome expectancy can be seen as a partial—though often trivial—determinant of efficacy expectancy in Bandura's model (Figure 4) in that one cannot feel capable of doing a behavior unless one knows the behavior and what its ordinary consequences are.

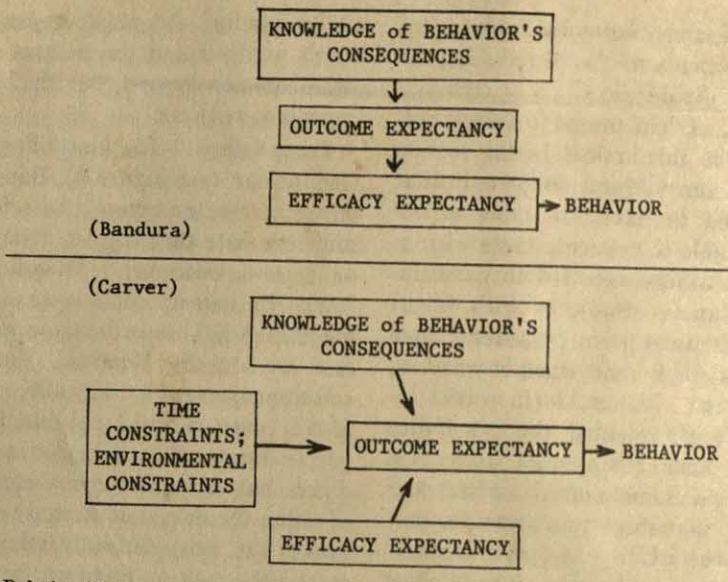

Figure 4. Relationships among outcome expectancy, efficacy expectancy, and behavior, as conceptualized by Bandura (1977) and Carver.

The models are in somewhat closer agreement with regard to the nature and determinants of efficacy expectancy. Bandura conceived of efficacy expectancy as being a product of four classes of information: prior performance accomplishments, vicarious experiences, verbal instructions, and emotional arousal. An additional set of relevant information would seem to be the degree to which one perceives that one can separate a behavior into components, each of which may be manageable by itself. These various sources of information (involving both previously encoded stimuli and presently experienced stimuli) are processed together, yielding a judgment of efficacy expectancy.

Role of emotional arousal. Even with regard to the determinants of efficacy expectancy, however, there is a point of conflict between the models: specifically, the role that is assumed to be played by the perception of emotional arousal. As was noted in the preceding paragraph, Bandura (1977) held that fear arousal was one kind of input into efficacy expectancy. Although this position has been moderated to take into account attributional contingencies (Bandura et al., 1977), there still appears to be a difference between Bandura's position and the position taken in the model proposed here. The present model holds that the role of perceptions of fear arousal in an approach attempt (initially, at least) is to cue the self-assessment process (see Figure 5). This assessment results in an outcome expectancy judgment, which for fear-based behavior is largely determined by efficacy expectancy (which derives, in turn, from the other informational sources enumerated by Bandura, 1977). This expectancy determines whether the person subsequently withdraws or returns to the approach attempt.

This analysis has received empirical support in three studies. Carver and Blaney (1977a, Experiment 3; 1977b) showed that persons who differed only in their chronic efficacy expectancies responded to false feedback of arousal in two quite different ways. Confident subjects focused on their approach attempt and were not debilitated behaviorally; doubtful subjects avoided focusing on the approach attempt and withdrew more quickly, compared to doubtful subjects given feedback of nonarousal. This interactive influence of fear perceptions on focus of attention and behavior—a set of findings that has subsequently been conceptually replicated using a self-awareness manipulation to heighten awareness of veridical fear (Carver et al., 1979)—does not seem easy to predict from Bandura's assumptions. The findings are, how-

ever, clearly predicted from the present model of self-attention processes.

Generality. A final useful comparison between the theories concerns their relative generality. Bandura's (1977) analysis was aimed quite explicitly at fear-related behavior and the therapeutic change of such behavior. In applying the two models to situations in which the likelihood of a positive outcome is entirely dependent on *intra*personal factors, which is the case in fear-based behavior, the two are functionally equivalent. This is true because outcome and efficacy expectancies as defined in the present model are perfectly confounded with each other in this particular class of situations. A consideration of broader contexts reveals, however, that the present model is more general in two respects than is Bandura's. First, because outcome expectancy is not held to be determined solely by knowledge of the task-appropriate behavior, the present model can generate predictions for two classes of behavioral interruptions not considered by Bandura: incomplete or inadequate behavior that occurred in the past and behavior constrained by environmental factors (see Figure 3). Secondly, since efficacy expectancy is held to exert an influence on behavior that is independent of outcome expectancy, the present model explicitly predicts that different affective experiences will be associated with similar behavioral events, based on differences in efficacy expectancy. That is, Proposition 13 above holds that if there is negative outcome expectancy, the presence of high efficacy perceptions predicts that affect will occur as resentment toward the environment; presence of low efficacy perceptions predicts negative affect associated with the self. If outcome expectancy is favorable, low efficacy perceptions predict that positive affect will be associated with the environment; high efficacy perceptions predict that the affect will be associated with the self. These

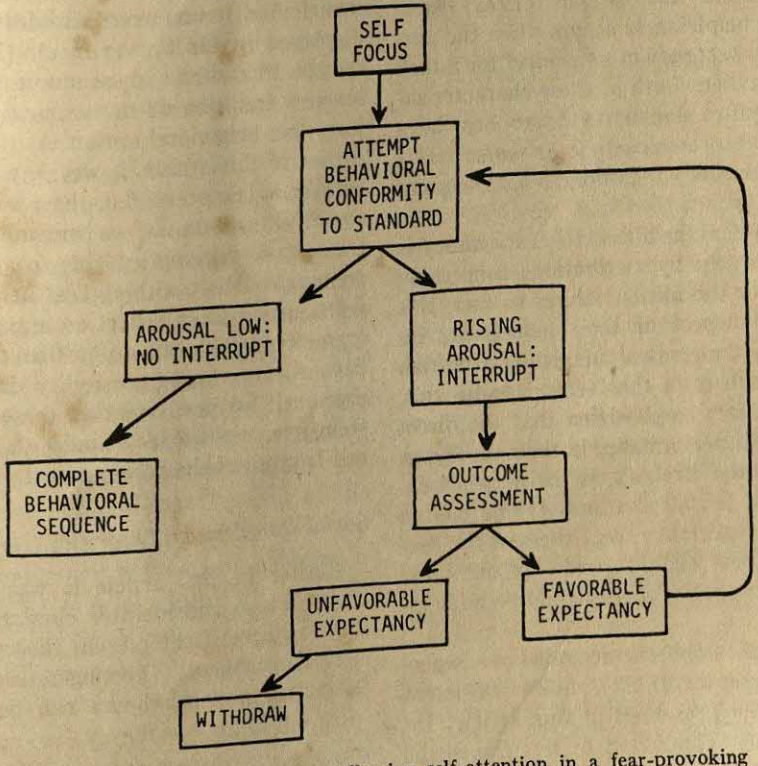

Figure 5. Information-processing sequence following self-attention in a fear-provoking behavioral context. (This sequence represents a specialized application of the model of behavioral regulation that was presented in Figure 3.)

predictions, which are now being tested, do not seem to be derivable from Bandura's (1977) theory.

Helplessness Theory

The present theoretical model also appears to have some implications for the area of research and theory known as "learned helplessness." Helplessness is a performance deficit that reflects presumed motivational, cognitive, or learning deficits resulting from fairly extended exposure to uncontrollable outcomes. There is at least one important similarity between aspects of the present model and the kind of cognitive analysis developed in recent years to account for helplessness effects among humans (e.g., Abramson et al., 1978; Wortman & Brehm, 1975). Abramson et al. (1978), for example, have proposed that the impact of uncontrollability on subsequent performance depends upon the development of an *expectation of future noncontingency*. Similarly, Wortman and Brehm (1975) have argued that helplessness occurs when the person has an *expectancy of no control* for a task being undertaken. Both of these characterizations are quite similar to what has been termed in the present article an *unfavorable outcome expectancy* regarding the subsequent task.

Abramson et al. held that this expectancy is influenced largely by attributions concerning the reason for the initial failure. In fact, this attributional aspect of their model has received by far the greatest amount of attention among researchers in that area. Despite this, however, it bears emphasizing that the direct determinant of performance in their theory, as in Wortman and Brehm's, is the person's expectancy, not the attributions. If one has an unfavorable expectancy, regardless of the reason, helplessness should result. If one's expectancy is favorable, there should be no helplessness.

The central emphasis accorded to expectancy by these theorists is quite consistent with the model presented in this article. Indeed, one study conducted to test the model (Carver et al., in press, discussed in detail earlier) could be regarded quite easily as a helplessness experiment. Subjects underwent a failure pretreatment, and some of them later displayed reduced persistence, which is often taken as a sign of helplessness. In providing support for the present model, that research thus also appears to offer support for other models of helplessness that rely on postulates about expectancies.

However, that research also suggests two respects in which the present model adds to such theories of helplessness. The more obvious contribution of this model stems from the fact that no other analysis of helplessness effects includes any consideration of the role of self-directed attention in promoting such effects. As is demonstrated in the Carver et al. (in press) research, that role may be quite an important one.

The second contribution of the present theory is its suggestion that the impulse to withdraw is basic to a wide variety of helplessness effects. The assumption of a withdrawal impulse is inherent in the present model. And it was overt withdrawal that was displayed in the Carver et al. (in press) research. In contrast, most studies in the helplessness tradition do not explicitly allow subjects this behavioral option. As was suggested earlier in this article, however, when physical withdrawal is prevented, the result may be a *cognitive* withdrawal—a mental dissociation from task attempts. This characterization seems consistent with typical helplessness effects, which often reflect an apparent unwillingness or inability to utilize task-relevant cues. An interesting possibility that should be examined further is that all these effects may stem from a thwarted impulse to remove oneself from the behavioral context.

Social Comparison Theory

Earlier in this article it was noted that there is also considerable similarity between some aspects of the present theory and social comparison theory (Festinger, 1950, 1954).[18] Social comparison theory can be viewed as

[18] Although this similarity exists for Duval and Wicklund's theory, as well as for the present model, this discussion will focus on the present model.

having three central assumptions. The first is that we tend to define much of reality—especially our social reality—by comparing our own opinions, reactions, characteristics, and capabilities with those of other people, usually termed *reference groups*. The second assumption is that the tendency to do this is exaggerated by conditions of ambiguity. The third assumption is that once consensus has been reached and some normative value implicitly established, then there is pressure toward conformity to this value among the members of the group.

Holding in abeyance the role of perceived ambiguity in the instigation of these processes, the elements of social comparison theory thus seem to fulfill two functions: first, to establish some value as a standard of comparison (by means of an implicit social consensus), and second, to increase behavioral conformity to that standard. These two functions are, of course, precisely the same as those assumed in a control-theory model of behavioral self-regulation such as the one proposed here. That is, a control-theory approach to motivation assumes two kinds of information-processing systems. The first of these is the system that analyzes and categorizes perceptual input, yielding a behavioral standard. The second system—a TOTE unit—regulates behavior with regard to that standard.

One way in which social comparison theory is similar to the model proposed here concerns the first stage of social comparison, in which a standard is established by implicit social consensus. This aspect of that model would seem to represent one important way in which a person can extract a behavioral standard through categorization of his or her environmental context (Propositions 2 and 3 of the present model). This may indeed be one of the most commonly used methods of choosing a behavior among human adults. In principle, however, it represents only a subset of a larger class of potential ways to determine behavior. Thus, it would seem that this facet of social comparison theory could be subsumed under the more general process of categorizing the nature of one's context (a process that certainly deserves much more attention than it has received in the present article).[19]

The second stage of the social comparison process, in which conformity pressure occurs, is also functionally similar to a major facet of the present model. The difference between the two is in the locus assumed for the impetus to conform. In the present model, the conformity tendency (via the normal matching-to-standard sequence) is construed as internally based. Discussions of social comparison theory, in contrast, often seem to assume the existence of external pressure to conform.

Finally, it seems worthy of brief note that a subsidiary aspect of social comparison theory holds that if a person cannot conform to the group's standard, there is a tendency for either the group or the person to withdraw from the other. This seems not unlike the present proposition that when one cannot match one's behavior to the standard—that is, when outcome expectancy is unfavorable—there is an impulse to withdraw from the attempt.

Summary and Concluding Comment

In the preceding pages, a cybernetic model of self-attention processes was presented, along with support for its propositions. Summarized briefly, self-focus in a context where no behavioral standard is salient leads to heightened cognizance of salient self-elements. Self-focus when a behavioral standard does exist leads to an automatic matching-to-standard sequence. This sequence is regarded as the realization within a psychological system of a negative feedback loop. If matching-to-standard is interrupted, an outcome assessment ensues. A favorable outcome perception

---

[19] The assumption in social comparison theory that ambiguity increases the tendency to undertake social comparison suggests another possibility not previously addressed in this article. That is, it may be a more general rule that ambiguity leads to increased information search, even when the context is nonsocial, in order to determine better what behavior is appropriate. This possibility certainly should receive more attention. If confirmed, it would further increase the degree to which these two analyses overlap.

leads to positive affect and/or to a return to matching-to-standard. An unfavorable outcome perception leads to negative affect and/or behavioral withdrawal.

Following presentation of the model, three specific points of conflict between this theory and self-awareness theory were addressed. In each of those cases, evidence was reviewed that indicated the present analysis to be the more internally consistent and parsimonious of the two. Comparisons also were undertaken between the present model and three other theories: Bandura's analysis of cognitive processes underlying fear-related behavior, helplessness theory, and social comparison theory. Each of those comparisons revealed the possibility for considerable integration between models.

There are many other potential links that could be developed between the present theory and information-processing ideas currently under investigation elsewhere in social and cognitive psychology. A fairly obvious example is the similarity between the propositions of the present model that concern salience of oneself versus the environment and research conducted on other kinds of salience phenomena (see, e.g., Taylor & Fiske, 1978). Although there simply is not the space to pursue those interrelationships here, the existence of such commonalities among theories suggests that the ideas on which the present model is based have a good deal of integrative potential. Indeed, this seems apparent even if one considers only the material discussed in this paper. The model of self-attention processes presented here has proven to be applicable to a wide range of phenomena, topics as diverse as taste and test anxiety, in a way that is internally consistent. It is to be hoped, moreover, that this perspective will prove to be useful in generating additional hypotheses, beyond those considered in the preceding pages. Thus might the specific ideas advanced here, and the concepts of control theory more generally, come to be seen as important tools for the analysis of a broad range of longstanding problems in human behavior.

Some Effects of Deception and Level of Self-Monitoring on Planning and Reacting to a Self-Presentation

Gregory C. Elliott
Department of Sociology
University of Maryland

This experiment addressed issues in impression management. First, this study investigated whether type of impression intended (accurate or fabricated) and level of self-monitoring (high or low) affect the amount of information about a target person that individuals would acquire, at some cost to themselves, prior to interacting with that person. As predicted, high self-monitors planning a fabrication purchased more information than high self-monitors planning an accurate impression or low self-monitors planning either type of impression. In addition, reactions of both participants to the actor's performance were analyzed. Impression type affected both actors' and targets' reactions, whereas self-monitoring affected only the targets' ratings.

Erving Goffman, in his seminal work on impression management (1959), has discussed how individuals present an impression of self that influences the definition of the situation that others come to formulate. It is in the various parties' best interest to induce others to attribute qualities to them that are supportive of their own interaction goals. People can do this by expressing themselves in a manner that communicates impressions intended to lead others to support their plans voluntarily. The current experiment focuses on actors' preparation for an upcoming encounter and reactions to their performance.

The experiment reported herein was conducted as part of a doctoral dissertation for the Department of Sociology, University of Wisconsin, Madison. The research was supported by National Institute for General Medical Science Grant GM-01526-11 and by the Small Grants Committee, Department of Sociology, University of Wisconsin.

Special thanks are due Shalom H. Schwartz and Elizabeth E. DeCourcy-Wernette for their patient counsel and constructive criticism. I also thank H. Andrew Michener, William Ickes, Jane Piliavin, Mark Snyder, John Fleishman, and the anonymous reviewers for their comments on earlier drafts.

Acquiring Information

Actors planning for an interaction can benefit from information about the other participants. They can use this information to help them tailor their impression to fit the particular characteristics of the encounter. In considering the problems of creating and sustaining an impression, one should distinguish between impressions that the actor believes to be accurate self-presentations and impressions that the actor knows are false (fabrications, in Goffman's, 1959, terms). Information about others is helpful in conveying an accurate impression (if only to ensure accuracy), but it is even more important in conveying a fabrication. Whereas an accurate impression can be generated from habit and previous experience, actors planning a fabrication must be wary of the possibility of being discredited. Behavior must be carefully monitored and, when necessary, accentuated or suppressed. Normal, habitual behavior that usually enhances an accurately descriptive performance could betray deceiving actors. Fabricators must be sensitive to elements of the encounter that could threaten or enhance their performance. In particular, information about the other participants in the interaction can indicate the kind of performance most likely to succeed.

There is evidence that individuals differ in the importance they attach to information about other participants. Snyder's (1974, 1978, in press) work on self-monitoring tendencies indicates that some individuals show a greater attentiveness to external cues (i.e., information from the environment in which an interaction occurs) when judging the appropriateness of an impression and the effectiveness of a performance. Labeled high self-monitors, they are concerned with the situational appropriateness of their behavior during a social encounter. As a result, they show greater sensitivity to the characteristics of others involved in the interaction, whether revealed by self-presentation or by inadvertence.

On the other hand, low self-monitors do not rely so much on social comparison information. Although they may also be concerned with their behavior in an encounter, they tend to rely on internal cues (such as internalized norms or attitudes) to guide their self-presentation.

It follows that high self-monitors should be eager to acquire information about other participants in the interaction. This should be especially true if they plan to convey a fabrication. The challenge of having to contradict their own attitudes or beliefs without revealing the contradiction makes them more careful than usual about their performance. This greater care manifests itself in part in an increased interest in information about other participants. Actors can use relevant information about others to plan their fabrication more precisely and to increase the likelihood of success.

On the other hand, individuals attentive to internal cues (low self-monitors) should feel little need for information about other participants, regardless of the type of impression to be conveyed. Their behavior is guided by their own beliefs about what is necessary to convey the intended impression, be it accurate or fabricated. Although they may feel increased concern in planning a fabrication, it is manifested in a more thorough introspection for guides to action, not in a need for information about others.

Prior research on the acquisition of information about other participants in an upcoming interaction is sparse. Snyder (1974) found that, compared to low self-monitoring subjects, high self-monitors spent more time looking at a sheet of majority responses to a personality inventory that they were filling out while preparing for an upcoming discussion. This information was obtainable merely by turning one's head to see the majority response sheet taped to the wall near the subjects.

Note that this activity involved no real effort on the subjects' part, because the information was readily available. Information more critical to the actor may be more difficult to obtain and may involve some cost. Two studies (Eiser & Eiser, 1976; Eiser & Tajfel, 1972) investigated subjects' preferences for different kinds of information about an opponent in upcoming bargaining sessions. Subjects could find out how much each potential outcome would cost the opponent in resources expended and how much the outcome was valued in terms of resources gained. Each piece of information was available at a set price. Subjects purchased more information about the values the opponents placed on outcomes than on the costs; this value–cost difference was larger in competitive than in noncompetitive groups.

These studies indicate that individuals who expect to interact with another do seek out information about them. Although the bargaining experiments do not explicitly involve impression management, self-presentational concerns could be one aspect determining subjects' behavior. The present experiment investigated the acquisition of information by individuals prior to conveying a specific impression of themselves to another person. It differs from Snyder (1974) in that the information was available only at some cost to the actors. Unlike the studies conducted by Eiser and associates (Eiser & Eiser, 1976; Eiser & Tajfel, 1972), the present study investigates information purchasing in an explicit context of impression management.

The arguments presented above lead to the following hypotheses. First, because of their greater sensitivity to external cues for appropriateness of behavior in everyday en-

counters, high self-monitors will seek out more information about another participant, even at some personal cost, than will low self-monitors. Second, the type of impression planned should influence the magnitude of the discrepancy between the information acquired by high and low self-monitors. A planned fabrication increases one's concern for performance during a self-presentation, which is reflected in a greater attentiveness to cues of situational appropriateness. For low self-monitors, this means more attention is paid to internal states, such as norms or personality characteristics, than would occur when planning an accurate impression. High self-monitors, by contrast, would be led to a greater reliance on information from the environment than would be required for an accurate performance. A two-way interaction between self-monitoring and impression type is therefore predicted: Prior to an accurate performance, high self-monitors should acquire more information about another than will low self-monitors, but the difference in the amount acquired should be even greater when planning a fabrication.

Reacting to the Encounter

This study also investigated the participants' reactions to the encounter. Actors could conceivably react to their behavior during the interaction on two distinct levels: their own personal feelings during the encounter (were they comfortable, confident, self-conscious?) and their feelings about the performance they have just completed (were they successful, organized, persuasive?). Individuals may be able to separate critiques of their own performance quality from the feelings they had while performing, although the two are not necessarily independent. In addition, other participants in the interaction should be able to make judgments about the actor on the same dimensions of performance quality and apparent feelings.

In prior research, Ickes and Barnes (1977) found that when high self-monitoring subjects were paired with self-monitoring partners in an informal interaction, high self-monitors rated themselves and their partners as more self-conscious than did low self-monitors. Regarding others' impressions of an actor's performance, Weiler and Weinstein (1972) discovered that accurate impression managers were judged more convincing than were fabricators.

Individuals conveying an accurate impression should feel little stress during the interaction. They have only to be themselves to keep the interaction proceeding smoothly. Fabricators, however, are under much more stress. They must constantly be alert for signals that their performance is being discredited. This leads to the hypothesis that actors who have just conveyed a fabrication will reveal more negative feelings about themselves and their performance than will those who have conveyed an accurate impression. Similarly, observers will evaluate the fabricating actors' performance more negatively than that of accurate impression managers, largely because of nonverbal leakage (Ekman & Friesen, 1969).

High self-monitors check their performance during an interaction by judging the others' reactions to them and tailoring their self-presentation accordingly; low self-monitors do not make much use of the reactions of others. Because high self-monitors are especially aware of the reactions of others, they are more critical of their performance than are low self-monitors. The hypothesis is that they will react more negatively than will low self-monitors. On the other hand, greater attentiveness to reactions of others spurs the high self-monitors to correct any problems in their performance quickly. As a result, the hypothesis is that observers will evaluate the performance of high self-monitors more positively than that of low self-monitors.

Method

Overview

Subjects were led to believe that they were participating in a study of impression *formation*. They were asked to help the experimenter discover how people build impressions of others by conveying a specific impression about themselves to a target person (ostensibly a naive subject, but actually a confederate). This impression was either in harmony with their own attitude (accurate impression condition) or contrary to it (fabricated impression condi-

tion). Subjects were told that the experimenter would be studying how the target person built an impression of them and what elements of the impression were important in the target person's mind.

A successfully formed impression would net both participants a monetary bonus. Before beginning the encounter, subjects were given the opportunity to purchase information about the target person by giving up some of the standard subject fee. After some time to prepare themselves, subjects spent 10 minutes in an informal face-to-face discussion with the confederate. Subjects and confederates then completed a questionnaire on which they rated the subjects' performance and feelings during the encounter.

Subjects

Sixty-six female students at a large Midwestern university served as subjects. All subjects had previously filled out preexperimental questionnaires. Two subjects were dropped from the analysis. One did not understand the instructions. A second refused in advance to be paid for her participation, commenting that this meant the information made available to her would cost her nothing. Since her orientation to the experiment was affected by her refusal to be paid, her responses were not comparable to the others.

Preexperimental Questionnaire

Six weeks before the experiment began, students from introductory sociology and education courses at the university filled out a preexperimental questionnaire. The questionnaire contained Snyder's (1974) Self-Monitoring Scale (labeled "personal reaction inventory") and a "critical issues inventory" that measured attitudes toward controversial issues. Two items on legalizing marijuana served as the basis for determining the accuracy of the impression to be conveyed. The items were scored from −3 (extremely unfavorable to legalization) to 3 (extremely favorable to legalization). Subjects receiving a summed score of 4 or more on these items were judged as definitely in favor of legalization and were eligible to participate in the experiment.

Design

The study utilized a 2×2 factorial design that varied type of impression (accurate vs. fabricated) and level of self-monitoring (high vs. low). The impression was accurate if the subject was asked to appear in favor of legalization; it was fabricated if the subject was asked to appear opposed to legalization. Subjects were high in self-monitoring if they scored above the median (12 in a possible range from 0 to 25) on the self-monitoring scale; they were low in self-monitoring if they scored below the median. Subjects were randomly assigned to the impression-type condition, with the constraint that in each condition half the subjects must be high and half must be low in self-monitoring. This yielded 16 subjects in each cell of the design. Confederates were randomly assigned to each condition.

Experimental Procedure

In a preparation room, the experimenter explained the (fictitious) nature of the study. The confederates were not present. The experimenter explained that this experiment was an attempt to discover how people form an impression about another when they are face-to-face with that person, and that the subjects would serve as a discussion partner with another woman. They were also told that the experimenter would find out if the other woman had formed specific impressions about the subject after the discussion had ended. Subjects were told they would be paid $2.50 for their participation. They then signed the participation consent form.

Next, the experimenter handed two instruction sheets to the subjects. The first described their task in general. Reading from the instructions, the experimenter explained that to ensure comparability across settings, the subjects' task was to convey a *specific* impression about themselves to their partner during a 10-minute, face-to-face conversation period. The specific impression dealt with marijuana legalization. The experimenter explained that he was interested in determining whether appearing to be for or against an issue influences how others build up an impression of people. Therefore, some would be randomly chosen to convey the impresson that they were in favor of legalizing marijuana use, whereas others would be randomly selected to appear opposed to it.

In addition, the experimenter told the subjects he was interested in whether the other person could build up an overall *favorable* picture of them at the same time she was learning whether they were for or against marijuana use. Subjects were asked to induce the other woman to like them, regardless of which side of the issue they were assigned. The purpose of this task was to keep the subject from merely stating her assigned views perfunctorily and to promote a more realistic conversation.

The experimenter explained that the other woman was the focus of the experiment. He said he would be analyzing exactly how she received the impression they would convey. The other woman (ostensibly) was with a (nonexistent) research assistant and had been told the study involved an analysis of what goes on in an informal, videotaped discussion of issues that affect college students' lives. The rationale for the 10-minute discussion was that it was a practice session to give the participants a chance to get used to the discussion.

Subjects were led to believe that the other woman had been given a list of possible discussion topics, including marijuana legalization. Since it was only one of several issues on the list, the subjects were told that they would probably have to bring up the topic themselves. They were told to do this in the manner most comfortable for them, as long as the

partner had a fair chance to build an impression of how they felt about marijuana.

The experimenter stressed that it was important that the partner not realize that the study was really about impression formation until it was actually over; otherwise, she might try too hard and do things she wouldn't do in normal, everyday life.

The second instruction sheet informed the subjects of some special considerations regarding their task. First, the experimenter was interested in more than whether their partner came to understand how they felt about legalization. Subjects were asked to build up in the other person's mind an organized, sensible set of reasons supporting their position. To help them, they would have available a list of some of the most common reasons given for the position they were assigned to convey.[1] The experimenter emphasized that their use of this list was entirely a matter for them to decide and that the quality of reasons used was at least as important as the quantity.

Second, subjects did not have to persuade the other person to agree with them. The experimenter was only interested in whether and how the partner came to understand what the subjects' position was.

Third, the subjects were told that success in forming impressions often carries some kind of benefit for those involved in the get-together. To simulate the real-life possibility of rewards, the subject and her partner would each earn a 50¢ bonus if the other woman formed *both* a clear impression of the subject's attitude toward marijuana legalization and an overall favorable impression of her. Success would be determined by the target person's responses to a questionnaire after the discussion.

Subjects were then taken to their separate interaction rooms, where the actual discussions were to take place. At this point, half the subjects learned that they were to convey the impression that they favored legalizing marijuana (an accurate impression), and the other half were to appear to oppose legalization (a fabricated impression). They were also given a list of 16 reasons supporting the assigned position. To this point, the experimenter had not known to which condition the subjects would be assigned. Throughout the study, the experimenter was blind to subjects' self-monitoring scores.

Dependent Variable

After considering their positions for a few minutes, subjects were given an opportunity to purchase information about their partner. Three kinds of information were available: biographical (e.g., hometown, religious preference), attitudinal (involving issues other than marijuana, e.g., abortion, the priority of conscience over law), and personality characteristics (e.g., assertiveness, tolerance for others). This information came from a self-descriptive questionnaire ostensibly being filled out by the other woman at that time. Actually, a standard response for each item was provided by the experimenter. These responses were neither extreme, in the case of the attitudinal and personality items, nor unusual, in the case of the background information.

For every 2 bits of information selected, 1¢ was deducted from the standard subject fee of $2.50. Ten bits of each type were available (a total of 30 bits), for a maximum possible cost of 15¢. Subjects were told that the cost was to simulate the real-life possibility that one could often find out about another only at some cost to the self. The experimenter emphasized that subjects were free not to purchase any information at all. They could have as little or as much as they wanted. Subjects were given a few minutes alone to decide, at which time the experimenter returned with the questionnaire (presumably filled out by the other person) and filled in any requested responses. The amount and kind of information bought by the subjects constituted the major dependent variable.

Performance Ratings

After being given 5 minutes to prepare, subjects engaged in an informal 10-minute discussion with the partner, who was brought to the subjects' room. The other woman was actually a confederate, chosen for her ability at improvisational drama.[2] She was trained to be easygoing, personable, and ambivalent regarding legalization. Although keeping up her end of the conversation, she did not direct nor dominate the conversation in any way. The confederates were blind to the impression-type manipulation and the premeasured attitudes of the subjects, as well as to the experimental hypotheses. Subjects were randomly assigned to a confederate.

Following the discussion, the subject and the other woman were separated, and each filled out the same questionnaire consisting of 30 bipolar adjectives in semantic differential form. Half of the items measured their impressions of the performance that the subject had just given (e.g., interesting, impressive); the rest measured their impression of what the subject had been feeling during the discussion (e.g., enthusiastic, self-conscious). These items constituted the measure of the second dependent variable.

At this juncture, the subjects were extensively debriefed. This involved assessing their suspicion level, discovering their perceptions about the experiment, revealing the true nature of the experiment, and ensuring that they felt comfortable about their participation. The experimenter then paid the subjects $2.50, cautioned them not to discuss the experiment, and dismissed them.

---

[1] The reasons were generated from two sources: Kaplan (1970) and the National Commission on Marijuana and Drug Abuse (1972).

[2] I thank Joyce Bizub, Mary Erdman, Laurie Franklin, Jane Homburg, Laura Raffe, and Dana Schwindt for serving as confederates. Their skill at improvisation added greatly to the believability of this experiment.

Results and Discussion

Internal Validity

During the debriefing, the degree of suspicion the subjects expressed was coded. Complete surprise upon learning the true nature of the experiment was assigned a value of 0; some vague feeling that something else was going on was assigned 1; the correct inference that the subjects themselves were at least part of the focus of the study received a 2; guessing in addition that the partner was a confederate received a 3; correctly discerning that the experiment investigated the subject's impression management behavior was scored 4.

Complete surprise was expressed by 60.9% of the subjects, and 26.6% had only a vague feeling that something else was going on. The mean level of suspicion was .61, indicating that most subjects believed the cover story they were given. Analysis of variance in suspicion using level of self-monitoring and impression type as factors revealed that no condition caused more suspicion than any other. In addition, dichotomizing subjects into nonsuspicious (those receiving a coded value of 0) and suspicious (those receiving any other score) created a factor that showed no main effects on the dependent variables, nor were any interactions between suspicion and the experimental factors in evidence.

Information Purchasing

The major dependent variable in this study was the amount of information purchased by subjects in preparing for their self-presentation. Recall that the available information was of several types. To see whether the effects of impression type and self-monitoring differed for each type of information, an analysis of variance was carried out, with the level of self-monitoring and impression type as between-subjects factors and information type as a within-subjects factor with three levels: biographical, attitudinal, and personality characteristics. The results of the analysis support the hypotheses. Analysis of variance in the total amount of information purchased revealed a significant main effect for self-monitoring, $F(1, 60) = 10.65$, $p < .002$, a marginal main effect for impression type, $F(1, 60) = 3.57$, $p < .07$, and a significant two-way interaction between these factors, $F(1, 60) = 4.25$, $p < .05$. The marginal values of Table 1 provide the means for each cell of the design. High self-monitoring subjects purchased more information than low self-monitoring subjects. Fabricating subjects showed a tendency to purchase more information than those conveying an accurate impression. High self-monitoring fabricators reliably bought more information than all others.[3]

An additional interesting finding was a three-way interaction between level of self-monitoring, impression type, and information type, $F(2, 120) = 3.213$, $p < .05$. Inspection of the means (provided in Table 1) revealed the pattern of this interaction. For low self-monitoring subjects, there were no differences in the amounts of information purchased. High self-monitoring subjects tended to buy the same amount of personality information, regardless of the truthfulness of the impression they were conveying; they tended to buy less biographical and attitudinal information when planning an accurate impression than when planning a fabrication.

It may be that, for the high self-monitors, what the other individual thinks she is like as a person is not differentially important in planning a performance. Personality characteristics are important elements of some baseline information about another, but they are probably not directly related to the issue at hand (at least not in this experiment). Personality information serves mainly to guide actors in choosing the general manner of self-presentation (i.e., orientation to the other)

[3] Inspection of the within-cell variances revealed that the assumption of homogeneity of variances was tenuous. The information purchased was transformed by the square root function, resulting in more homogenous cell variances. The analysis of variance for this transformed variable did not change the significance levels of any of the effects. Since the effects are more readily interpretable for the untransformed variable, results are discussed in terms of it. An analysis of variance was conducted using confederate as an additional between-subjects factor. Results showed no effects for confederate, alone or with any of the other factors.

Table 1
Mean Number of Information Bits About the Partner Purchased by Actors as a Function of Impression Type, Level of Self-Monitoring, and Information Type

Information type	Impression type: Accurate	Impression type: Fabricated
High self-monitoring

Note. Means that do not share a subscript differ from each other at the .05 level of significance by the Newman–Keuls procedure.

and not specific elements of the performance. Therefore, personality information is equally important in conveying an accurate or a fabricated impression.

Attitudinal and biographical information is more directly related to the issue at hand. These data give indications of how one might feel about the issue around which the impression is being built. This would be especially important for a fabrication. High self-monitoring actors in a fabrication are feeling their way through unfamiliar territory and need relevant information about their partners. With an accurate impression, high self-monitors can rely on their abilities as performers. The luxury of being themselves may lend high self-monitors the confidence to do without this information and deal with contingencies as they arise. In short, a fabricated impression is more of a challenge to high self-monitoring actors than is an accurate impression.[4]

One might ask if the difference between high and low self-monitors was due to the fact that low self-monitoring actors felt no heightened concern when contemplating a fabrication. Although no data from this experiment directly addressed this question, some indirect evidence suggests that this was not the case. All subjects judged the accurate performance as easier ($M = 3.97$) than the fabricated one ($M = 1.87$), $F(1, 60) = 12.53$, $p < .001$, and there were no such differences between high and low self-monitors, $F(1, 60) < 1$. It is probable that all subjects anticipated difficulty with a fabrication. Because low self-monitors rely on their own internal states for resources, however, the challenge afforded by a fabrication did not motivate low self-monitoring actors to acquire more information about their partner.

Reactions to the Performance

The second set of hypotheses focused on the aftermath of the self-presentation. Actor subjects and observer confederates were given two sets of 15 bipolar items in semantic differential format to record their impressions following the encounter. Responses were made on a 9-point semantic differential scale. For purposes of analysis, a score of 9 was given to the positive extreme and 1 to the negative extreme.

It should be noted that confederate ob-

[4] This explanation is entirely post hoc and should be taken with some caution. One factor that adds to the tentativeness of this reasoning is that for the low self-monitors, a floor effect is operating: They cannot buy fewer than zero pieces of information. However, tests for the differences between accurate and fabricated impression type were conducted within each level of information type using only high self-monitors. In a test for "simple effects" of impression type (cf. Kirk, 1968, chap. 8), the results indicated significant differences ($p < .05$) in the amount of biographical and attitudinal information purchased by accurate and fabricating subjects; there was no difference with respect to personality information.

servers' ratings of the subjects' performance quality were their own personal judgments of what they saw; their ratings of the subjects' feelings during the interaction were what the subjects were *apparently* feeling, as revealed by their verbal and nonverbal behavior. Further, subjects and confederates completed these items while totally isolated from each other, with no way of influencing each other's ratings. Subjects were not told that they would be rating themselves until after the discussion was over, nor did they know that the confederate had rated them until the debriefing. Confederates were not told that the subjects had rated themselves until the last subject had been run. Finally, it should be recalled that the confederates were blind to all experimental conditions, so that any differences due to these factors must have been communicated through the performance.

Because of the large number of evaluations being made (30 each for subject and confederate), subjects' and confederates' ratings were factor analyzed separately using Rao's uniqueness rescaling procedure with varimax rotation. This served to organize the evaluations, reduce the number of analyses conducted, and ensure that the variables to be analyzed were relatively orthogonal.

Results for subjects' self-reports revealed three factors for the performance quality ratings and four factors for the feeling states ratings. For the performance quality items, Factor 1, an acting-quality factor, consisted of the items unconstrained–constrained, satisfied–dissatisfied, and graceful–awkward. The second factor reflected organization and included organized–disorganized, systematic–unsystematic, clear–unclear, impressive–unimpressive. Factor 3 indicated communicative quality, with consistent–inconsistent, understood–misunderstood, and persuasive–unpersuasive loading on this factor.

For the feeling states items, the first factor seemed to reflect satisfaction with the performance: positive–negative, capable–incapable, satisfied–frustrated, commendable–reprehensible, and enthusiastic–apathetic. The second factor was a security factor: calm–nervous, comfortable–uncomfortable, secure–insecure, and confident–unconfident. Factor 3 was a friendliness factor and consisted of friendly–unfriendly and likable–unlikable. Finally, Factor 4 seemed to reflect personal comportment: sensible–foolish, straightforward–devious, and free–constrained.

Turning to the confederates' evaluations of the subjects, four factors emerged from the ratings of performance quality. Factor 1 indicated performance competence: interesting–uninteresting, impressive–unimpressive, successful–unsuccessful, satisfied–dissatisfied, and believable–unbelievable. The second factor involved aesthetic reactions to the performance and consisted of organized–disorganized, graceful–awkward, flawless–flawed, and systematic–unsystematic. Factor 3 involved communicative clarity, with understood–misunderstood and clear–unclear. Factor 4 reflected performance coherence: persuasive–unpersuasive and consistent–inconsistent.

For the feeling states items, five factors were discovered. Factor 1 consisted of items dealing with the actors' perceived comfort in the role: calm–nervous, comfortable–uncomfortable, and free–constrained. Items loading on Factor 2 suggested personal accomplishment: commendable–reprehensible and capable–incapable. Factor 3 involved security, with secure–insecure, unself-conscious–self-conscious, confident–unconfident, and satisfied–frustrated. The fourth factor indicated friendliness: likable–unlikable, friendly–unfriendly, and sensible–foolish. Finally, Factor 5 suggests role commitment: enthusiastic–apathetic and positive–negative.[5]

A second-order factor analysis was run on

[5] As the reader may have noted, the factor structures for the two rating sources (subject and confederate) are somewhat different. The difference appears to reflect the perspective each brings to the performance. The factor structure for the actor subjects indicates their concern for the technical qualities of the performance. By contrast, the factor structure for the confederates reveals their critical reactions to the aesthetics of the performance. Such a performer/audience difference in perspectives is consistent with the dramaturgical approach to social interaction. However, it should be noted that the experimental design may have contributed to this difference. The observers were confederates of the experimenter and as such may have felt more like an audience than a coparticipant in the interaction.

the entire set of factors separately for subjects and confederates.[6] Variables used in the second-order analysis were obtained by summing the scores for the items loading on the same factors. For the subjects, analysis of the seven first-order factors yielded three second-order factors. Factor 1 involved performance competence, performance satisfaction, security, and personal comportment (performance quality first-order Factor 1 and feeling states first-order Factors 1, 2, and 4) and may be labeled a performance enactment factor. Factor 2 included organization and communicative quality (performance quality first-order Factors 2 and 3), which appears to deal with the mechanics of the performance. Factor 3 was the friendliness factor (feeling states first-order Factor 3).

For the confederates' ratings, analysis of the nine first-order factors also produced three second-order factors. Factor 1 involved performance competence, performance aesthetics, communicative clarity, performance coherence, and personal accomplishment (all the performance quality first-order factors plus feeling state first-order Factor 2) and indicates a critical evaluation of the performance. Factor 2 included comfort in the role, security, and role commitment (feeling states first-order Factors 1, 3, and 5), which appears to reflect a critical evaluation of the actors' personal fit to the role requirements. Finally, Factor 3 was the friendliness factor (feeling states first-order Factor 4).

Analysis of variance was conducted on the second-order factors. Variables were created by summing the scores for the items loading on the same factor. Results provide moderate support for the hypotheses. The subjects' second-order factors were relatively unaffected by the experimental conditions. No effects for level of self-monitoring achieved statistical significance. Impression type affected only the performance enactment factor (Factor 1). Subjects rated their performance enactment more positively for an accurate impression ($M = 100.31$) than for a fabrication ($M = 88.44$), $F(1, 60) = 6.64$, $p < .025$.

The experimental conditions had greater influence on the confederates' second-order factors. Level of self-monitoring affected all three factors. For the performance evaluation factor (Factor 1), confederates rated high self-monitors more favorably ($M = 108.41$) than low self-monitors ($M = 93.72$), $F(1, 60) = 6.82$, $p < .025$. High self-monitors were also seen to fit the role they enacted (Factor 3) better than low self-monitors ($M = 65.59$ for high self-monitors vs. $M = 59.53$ for low self-monitors), $F(1, 60) = 3.97$, $p < .06$. Finally, high self-monitors were seen as friendlier (Factor 3; $M = 23.62$) than low self-monitors ($M = 22.19$), $F(1, 60) = 4.05$, $p < .05$, a result also reported in Lippa (1976).

Impression type influenced the confederates' ratings on two second-order factors. Accurate impression managers were judged by the confederates to fit the role (Factor 2) better ($M = 65.69$) than fabricators ($M = 59.44$), $F(1, 60) = 4.22$, $p < .05$. In addition, they tended to see accurate impression managers as friendlier (Factor 3; $M = 23.59$) than fabricators ($M = 22.22$), $F(1, 60) = 3.71$, $p < .06$.

Although the targets seemed sensitive to many aspects of the actors' performances, one exception stands out. They did not seem to realize when the actors were deceiving them. Observers rated fabricators as no less straightforward or believable than accurate performers were. Believability *was* affected by the level of self-monitoring. High self-monitors were rated as more believable ($M = 7.47$) than low self-monitors ($M = 6.03$), $F(1, 60) = 5.95$, $p < .02$.

Apparently, actors were able to look fairly convincing during the discussion. They did not

[6] A second-order factor analysis was conducted using all 16 factors extracted for both subjects and confederates. The results yielded 4 second-order factors. Factor 1 consisted of all the confederates' first-order factors. Factors 2, 3, and 4 were identical to the 3 second-order factors reported in the analysis involving only the subjects' factors. Because there was no mixing of first-order factors across rating source in the second-order structure and because separate analyses of the subjects' and confederates' factors yielded identical results in the subjects' case and more differentiated results in the confederates' case, it was decided to use the second-order factors from the separate analyses as dependent variables in the analyses of variance.

fool themselves, however. Actors in the fabricating condition reported themselves as less straightforward ($M = 5.94$) than those conveying an accurate impression ($M = 7.34$), $F(1, 60) = 5.48$, $p < .05$, and slightly less believable ($M = 7.09$ for fabrication vs. $M = 7.81$ for accurate impression), $F(1, 60) = 3.26$, $p < .08$.

Compare these results to those in Lippa (1976), in which subjects sequentially role played teachers as introverts, extraverts, and themselves. Although rating high self-monitors as more technically proficient actors, observers were better able to detect their true tendencies toward extraversion. The correlation between perceived and actual (as assessed by premeasures) extraversion was greater for high than for low self-monitors. In other words, high self-monitors were perceived more accurately than low self-monitors. Perhaps the difference is due to differences in the content of the self-presentation. In the present study, attitudes were being conveyed; in Lippa's study, the content of the impression was a personality characteristic. Expressive control for the latter might be much more difficult.

Conclusion

The results of this study indicate that actors involved in planning a self-presentation exhibit differential interest in information about a prospective interaction partner. A person variable (self-monitoring) and a situation variable (impression type) combined interactively to influence the amount of information acquired by impression managers. Specifically, only high self-monitors who planned a fabrication tended to purchase information about their prospective partner. Further, whereas low self-monitors found all types of information unnecessary, high self-monitoring actors placed different values on the kind of information available. High self-monitors acquired personality information about their partner regardless of impression type but purchased attitudinal and biographical information only when planning a fabrication.

This study also investigated actors' and observers' reactions to the actors' performance. One striking result is the degree to which subjects' self-reports were unaffected by the experimental conditions. In particular, high self-monitors rated themselves no better or worse than low self-monitors did. But confederates clearly distinguished between them, consistently evaluating high self-monitors more positively. This suggests that although high self-monitors may have been as worried as their low-scoring counterparts, they managed to hide those worries from their partner.

Several aspects of this experiment may limit the generalizability of the results. First, it may be that the results presented above apply only to those individuals whose true attitudes favor the issue involved in the performance. It should be recalled that all subjects were selected for their strong support for legalizing marijuana, a popular stand on college campuses. Perhaps the behavior of fabricating actors was due to being seen as supporting an unpopular position as much as to giving a deceptive performance.

Second, the impression to be conveyed was assigned by the experimenter and was not chosen by the actors themselves. It may be that the effects due to impression type were actually a function of a forced fabrication. Actors assigned a truly self-descriptive impression may behave no differently than they would if they had selected the impression themselves; actors assigned a fabrication may behave differently, more because they had no choice in the matter than because the impression was not honest. There are situations in which demands for a particular impression are strong enough so that very little choice exists. If the goals desired from the interaction are important, actors may be induced to enact the impression demanded by the situation, even if it involves a fabrication. Their plight would be not unlike that of fabricating subjects in the present experiment.

In sum, the results of this study suggest that impression managers are differentially concerned with acquiring information about another participant in an upcoming interaction. High self-monitors planning a fabrication are the only actors who acquire a significant amount of information about the other. More important, they will endure some personal

costs to obtain this information. They apparently believe that the advantages of additional information in preparing a self-presentation outweigh the costs of obtaining it. In the present study, individuals acquired information without the other's knowledge. It would be interesting in future research to learn if high self-monitoring fabricators maintain their interest in purchasing information when the other knows what is being acquired and at what cost. Further insights into the planning of a self-presentation will provide greater understanding of the process guiding impression management.

Effects of Speech Style and Sex of Speaker on Person Perception

Nora Newcombe and Diane B. Arnkoff
Pennsylvania State University

Lakoff has suggested that men and women use different speech styles, with women's speech more polite but less assertive than men's. The assumption that three of Lakoff's linguistic variables (tag questions, qualifiers, and compound requests) affect person perception in these ways was tested. Sex of speaker was also varied. In Experiment 1, undergraduates rated the assertiveness, warmth, and politeness of two male and two female speakers who used or did not use the three linguistic forms. All three "female" linguistic forms were rated less assertive than corresponding "male" forms; qualified speech and compound requests were rated warmer and compound requests more polite. Sex of speaker was a significant factor in only one possible comparison. These results were substantially replicated in Experiment 2, in which older and/or less educated women acted as judges. These findings suggest that Lakoff's intuitions concerning effects of speech styles on person perception are largely correct and that modification of speech styles could allow men and women to affect how they are perceived.

Our impressions of other people are derived from many sources: what they say, what they do, what others think of them, and so on. What people say is surely an important source of information, but *how* they say it may also be of great importance. Thus, for example, a rapid speech rate leads to higher ratings of speaker competence (Smith, Brown, Strong, & Rencher, 1975) and increases the persuasiveness of a communication by enhancing speaker credibility (Miller, Maruyama, Beaber, & Valone, 1976). The present article focuses on three linguistic dimensions that are hypothesized by Lakoff (1975) to affect person perception. According to Lakoff, the three forms are used differentially by men and women, thus contributing to the maintenance of stereotypes concerning sex differences in personality.

Lakoff has suggested that men and women differ in their styles of speech in ways that both result from sex stereotypes and reinforce those same stereotypes. Specifically, sex differences in speech styles are said to contribute to maintaining images of men as assertive, self-confident, and definite, and images of women as vague and lacking in confidence. Women's speech is also said to be more polite, in the sense of being more formal and more deferential than men's. The differences in speech style Lakoff discusses include the following linguistic dimensions, among others:

1. Greater female use of tag questions at the end of declarative sentences, for example, "It's really cold in here, isn't it?" Tags request listener confirmation of the truth of an assertion and are thus said to indicate lack of

We thank Cindy Allen, Kathy Malloy, and Carolyn Brodbeck for administering procedures; Cynthia Marsh, Ann Greeley, and Lillian Shermaski for assistance in coding the informally reported speech production study; Rus Bauer, Don Hallett, Debbie Northwicke, and WMAJ Radio for help in making tapes; and Alvin Rosenthal and James Rosenberger for statistical advice. David Siegler discussed the studies with us, and Carolyn Sherif and Martha Zaslow provided critical comments on the manuscript. Portions of this research were presented in a paper titled "Speech Styles and Sex Stereotypes" given before the Association of Women in Psychology, Pittsburgh, March 1978.

confidence. They are also characterized as polite in that they allow the listener a graceful "out" in case of disagreement.

2. Greater female use of hedges or qualifiers, that is, words or phrases such as "y'know," "kinda," "I guess," or "maybe," which blunt the force or definitiveness of an assertion but, again, are polite in that they give the listeners options if they wish to disagree with or ignore the statement.

3. Greater female use of compound requests (e.g., "Won't you close the door?") rather than simple requests (e.g., "Close the door"). Such forms are said to soften the assertion of power entailed in commanding or requesting action, as well as being considered more polite.

While these are interesting hypotheses with a variety of social implications, Lakoff has presented no empirical evidence to support her claims. She makes at least three assumptions based on intuition. First is the assumption that there are, in fact, differences in the frequency of use of the above-mentioned words and syntactic constructions as a function of sex. Second, Lakoff assumes that these linguistic differences influence how people are perceived, in the ways she has suggested. Third, Lakoff seems to assume, although she is inconsistent on this point, not only that linguistic style affects person perception but that style is an *important* influence on person perception.

The experiments to be reported in this article concern the second and third assumptions. However, we will first review evidence concerning the first assumption, that there are sex differences in linguistic usage. While this is not critical for our purposes, since the effects of individual linguistic variations are of some interest in their own right, much of the current excitement concerning Lakoff's proposals depends on the assumption of sex patterning. The data to date are somewhat contradictory. Several studies have failed to find sex differences, but there is growing evidence that such differences do exist, although perhaps only in certain contexts or for certain populations.

While Dubois and Crouch (1975) found 33 tag questions from males, but none from females, on tapes of question periods following formal presentations at a professional meeting, they did not provide information on number of participants or total time talking for each sex. Perhaps very few females were present, or those present talked very little in any style. Furthermore, an academic population may have distinctive speech styles. Lakoff (1975, 1977) has discussed at some length her belief that academic men are exceptions to her rules and use a speech style generally identified as "female." Many of the same reservations can be expressed about another study reporting no sex differences in the use of tag questions (Baumann, 1976).

Another study finding no sex differences was conducted by the present authors (Newcombe & Arnkoff, Note 1). Pairs of unacquainted undergraduates were taped while talking about three topics of general interest. The tapes were coded for instances of tag questions and qualifiers, as well as for other language differences discussed by Lakoff: rising intonation on declarative sentences, *so* and *such* as intensifiers, "cute" adjectives of admiration, and expletives and euphemisms. No differences in speech style or trends to differences were observed due to sex of speaker, sex of listener, or the interaction, either for frequencies or frequencies divided by time speaking.

There might, of course, be a variety of reasons for the lack of sex differences in linguistic form usage in this study, with perhaps the most obvious being the use of a college student population. However, sex differences in speech style were found in a very similar study by Crosby and Nyquist (1977, Study 1) that coded use of empty adjectives, tag questions, hedges or qualifiers, and *so*. McMillan, Clifton, McGrath, and Gale (1977) also reported differences between the speech of male and female college students, with women using more tags, more imperatives in question form, more intensifiers such as *so* and *such*, and more modals such as *might have said* (a dimension discussed by Key, 1975). McMillan et al. placed their subjects in a group problem-solving situation. Either being in a group or being in a problem-solving situation could potentially account for the appearance of sex-related linguistic differences. McMillan et al.

also found that sex differences were especially marked in comparing speakers from mixed-sex rather than same-sex groups.

Hartman (1976) found that in individual interviews, women aged 70 years or over used more tag questions and qualifiers compared to men of similar ages. Crosby and Nyquist (1977, Study 3) found that female clients requesting aid or information in a police station used "female register" (i.e., tag questions, hedges or qualifiers, and politeness expressions) more than male clients, and that female police personnel also used this style more than male police personnel. However, Crosby and Nyquist (Study 2) did not find sex differences in requesting assistance at an information booth. Gleason and Weintraub (1978) reported that mothers produced twice as many tag questions as fathers in speech to preschoolers, that fathers produced more simple requests than mothers, and that male day-care teachers produced more simple requests than female teachers. Further work is clearly needed to identify whether, and in what ways, variations in context, age, and other considerations determine the appearance of sex-related differences in language; that they do exist in at least some instances seems fairly well established.

There is relatively little direct evidence bearing on the second of Lakoff's assumptions, that differences in usage contribute to how people are perceived. While Bates (1976) has provided evidence that interrogative requests in Italian are judged to be more polite than simple imperatives, and Siegler and Siegler (1976) have found a nonsignificant trend for tag questions to be judged less intelligent than assertions, both studies involved judgments of a small sample of written sentences, with attention implicitly or explicitly drawn to the dimension of interest. We do not know from these studies whether linguistic form affects person perception in a more realistic speech context when attention is not focused on the forms and dimensions of interest.

Erickson, Lind, Johnson, and O'Barr (1978) have compared reactions to simulated court testimony delivered either in "powerful" or "powerless" style. These styles contrasted three of the dimensions discussed by Lakoff, hedges or qualifiers, intensifiers, and question intonation in normally declarative contexts. However, in addition, powerless speech contained many hesitation forms, such as pauses, stutters, and "uhs," incorrect or informal pronunciation, using of *sir* in addressing the attorney, and instances in which the witness asked the lawyer questions. Speakers using powerless speech were rated less credible and less attractive than those using powerful speech. While these findings indicate the general importance of speech style in impression formation, unfortunately they do not allow specific identification of which of the many contrasting speech dimensions were responsible for the effects observed.

It should be noted that some of Lakoff's claims regarding the effects of speech style in person perception are not obvious. For instance, tag questions, rather than conveying uncertainty, can be used in a condescending or overbearing manner to forestall opposition (Dubois & Crouch, 1975). If it is said with appropriate intonation, the statement "That production of Hamlet was *dreadful*, wasn't it?" can in fact be intimidating rather than uncertain.

With regard to Lakoff's third assumption, it seems important to determine whether speech style is a reasonably large determinant of person perception compared to the effect of sex stereotypes per se. According to Valian (1977), Lakoff is inconsistent in her position on the relationship of linguistic change to social change. She sometimes argues, as in her discussion of the term *Ms.*, that linguistic change can only reflect social change, not produce it. However, at other points she implies that changes in speech style could lead to changes in person perception large enough to be socially important. Whether the latter is the case would seem to depend in part on whether sex stereotypes are so powerful that most men would be seen as more assertive than most women, with speech style a relatively minor source of individual variation within sex.

The present studies were designed to examine the second and third assumptions regarding the effect of linguistic form on person perception. Ratings were obtained of the as-

sertiveness, politeness, and warmth of male and female speakers who used (or did not use) tag questions, qualifiers, and compound requests. The existence and nature of the hypothesized influence of the linguistic variables on person perception could thus be assessed, and the size of any effect could be evaluated relative to the effect of sex of speaker. Warmth was included in part because Lakoff alludes to women's speech as sharing greater sympathy, friendliness, and person orientation than men's and also because McMillan et al. (1977) suggest that Lakoff has overemphasized the negative connotations to women's speech and underemphasized its value in conveying interpersonal sensitivity. It would have been interesting to obtain ratings of femininity also, since Lakoff maintains that women who deviate from female style pay the price of being perceived as unfeminine. However, inclusion of such a scale would probably have sensitized subjects to the variable of sex of speaker and the general purpose of the study, thereby creating demand characteristics that would have invalidated results.

Following the rating task, subjects were also asked to estimate the relative frequency with which male and female speakers used tags, qualifiers, and compound requests. Siegler and Siegler (1976) have found that when asked to guess about sex, raters attribute tag questions to women and strong assertions to men. One purpose of the present studies was to determine whether sex stereotypes affect people's abilities to judge frequency differences. As Thorne (1976) suggests, if sex stereotypes override what people actually hear, Lakoff may herself have been biased in assuming that there are linguistic differences between male and female speech.

Having subjects rate spoken material leaves open the possibility that any effects found for sex of speaker will be due to differences in intonation, phrasing, or other vocal factors, rather than to subjects' sex stereotypes. Two speakers of each sex were used in an attempt to reduce the likelihood that effects of sex of speaker would be attributed to one individual's vocal characteristics, but clearly both males might differ from both females in some crucial respects. Written presentation would avoid the problem but would be a far less naturalistic technique. In any case, in these initial experiments the concern was to evaluate the effects, if any, of a variable over which people have some control (speech style) as compared to the effects of a set of variables over many of which they have no control (their sex) or relatively little control (e.g., pitch of voice can be controlled, but only within certain limits).

Experiment 1

Method

Subjects

A total of 138 undergraduates, 75 males and 63 females, participated in order to gain extra credit for a course in introductory psychology. Data from 58 subjects were later discarded to create an orthogonal design (see *Results* section for justification). Subjects were randomly assigned to one of 13 mixed-sex groups. Each group listened to one of eight versions of the stimulus material, with more than 8 groups necessary in order to obtain a minimum of 5 subjects of each sex listening to each version. The groups ranged in size from 6 to 15 people.

Stimulus Material

There were three linguistic variables of interest: tag questions, qualifiers, and compound requests. For each category, 16 *speech segments* (speech excerpts that could be part of an ongoing conversation) were written. Each was one to three sentences long and could plausibly either include or omit the words or phrases of interest. Items were chosen from a pool written by four people, after first discarding any items judged by any one of the four to involve a sex-typed topic. All tag-question items involved an inanimate third-person subject, such as a car, a movie, or a building, about which some aesthetic or practical judgment was being made. A sample item is: "My typewriter's finally been fixed. It sure took long enough (didn't it?)." Qualifier items used one of four words or phrases: *maybe, sort of, probably,* or *I guess*. A sample item is: "That's (sort of) a crazy reason for quitting school." Compound requests involved the insertion of either *will you* or *would you* before a simple imperative. Neither form included the word *please*. A sample item is: "(Will you) order me a pizza; I'll be there soon." [1]

[1] A complete list of the 48 sentences used in the experiment is available from the first author.

Two male and two female speakers recorded eight versions of the 48-item script (16 items for each of the three linguistic variables). Speaker identity was treated as a separate factor in analysis, nested within sex of subject. The speakers were in their twenties and were chosen on the basis of having no accent to the Northeastern ear, typical voice pitch for their sex, and some acting ability, although none were professional actors.

Eight versions were recorded so that each segment would be available in each of the two possible linguistic versions and would be recorded by each of the four speakers. The order of topics spoken about was constant across versions. Each of the linguistic forms (tag questions or corresponding assertion, qualified assertion or corresponding unqualified assertion, and compound request or correspondingly simple request) appeared once in each block of 6 segments, so that linguistic forms would be evenly distributed over the tape and the salience of each would be reduced. Speakers were assigned to segments so that no more than 2 successive segments were recorded by the same speaker and so that each of the four speakers recorded each of the six linguistic types once in the first half and once in the second half of the 48-segment tape.

Each subject thus heard, in a random order, 16 simple assertions (which could be considered buffer items), 8 assertions with tag questions, 8 assertions with qualifiers (one of four words), 8 simple imperatives, and 8 imperatives expressed as questions (one of two ways). This linguistic variety, combined with the variety introduced by the use of four speakers, reduces the likelihood that subjects noticed the linguistic variations and recognized that the study concerned reactions to these variations.

Procedure

Subjects were recruited for a study of "effective telephone communication." On arrival, they were told that the experimenters were interested in how people can communicate effectively when speaker and listener cannot make normal use of nonverbal cues such as facial expressions and gestures. Subjects were told that they would listen to a tape of 48 short segments of conversation recorded by people simulating telephone communication and were informed: "After listening to each segment, you will be asked to give your impression of the person talking. Specifically, you will be asked to rate the person's assertiveness, politeness, and warmth on a scale running from 1 to 10." Assertiveness was explicitly defined as "different from aggression—an assertive person doesn't have to sound belligerent or mad. But they do sound definite about what they want, rather than unsure or tentative." Subjects then signed an informed consent form, noted their sex and group number on an answer sheet, and proceeded to listen to the tape and make ratings. The experimenter stopped the tape recorder after each segment and allowed all subjects as much time as they desired to make the ratings.

Following this, another answer sheet was circulated, on which *tag question, qualifier,* and *compound request* were defined. The subject was asked to indicate for each form whether it had been used more by males, more by females, or equally by both. Subjects were then told the true purpose of the study and were given extra-credit cards.

Design

The ratings part of the study consisted of three parallel "studies," of tag questions, qualifiers, and compound requests. Each consisted of a Sex of Subject (2) × Sex of Speaker (2) × Linguistic Type (2) × Identity of Speaker (2) × Sentence Topic (i.e., stimulus sentence) (16) multivariate analyses of variance design with three dependent variables. All independent variables except sex of subject were manipulated within subjects, and identity of speaker was nested within sex of speaker. The three dependent variables were the ratings of assertiveness, warmth, and politeness on a 10-point scale, with higher ratings indicating higher levels of each quality.

Results

Rating Data

A total of 138 subjects participated in the study, but there were not equal numbers of each sex listening to each of the eight versions. The number of subjects of each sex per version ranged from 5 to 14, with a median of 8. With such a highly unbalanced design, it is likely that the order in which the variables were considered would seriously affect the results. Therefore an orthogonal design was created by discarding some subjects. Fifty-eight of the 138 subjects were randomly eliminated to leave 5 subjects of each sex for each of the eight versions. The following analyses are based on data from 80 subjects, 40 males and 40 females. No effects of version of the tape were observed in preliminary analyses, and this factor was thus dropped in the analyses reported below.

The three rating scales were correlated with each other (for assertiveness and politeness, Pearson $r = .27$; for assertiveness and warmth, $r = .18$; for politeness and warmth, $r = .81$), and thus multivariate analyses were performed on these data. The analyses were performed using the analysis of variance procedure of the Statistical Analysis System (SAS) statistical package (Barr, Goodnight, Sall, & Helwig, 1976).

Tag questions. The multivariate analysis showed a significant effect of linguistic form, Hotelling $T^2 = 31.77$, $F(3, 76) = 10.32$, $p < .0001$, and of sentence topic, Hotelling-Lawley trace = 2.64, F approximation $(45, 224) = 4.38$, $p < .0001$. Univariate analyses showed that tag questions were seen as less assertive ($M = 6.1$) than corresponding nontags (M rating = 7.2), $F(1, 78) = 20.27$, $p < .0001$. Sentence topic had a significant effect in all three analyses, of assertiveness, warmth, and politeness ratings. However, it is important to note that this heterogeneity in stimulus materials did not interact with or qualify any of the variables of interest (all Fs < 1). The only other significant univariate effect was that female subjects rated speakers as warmer than did male subjects, $F(1, 78) = 4.49$, $p < .05$, with ratings of 5.3 from females and 4.9 from males. However, sex of subject was not significant in the multivariate analysis or in the following two analyses of qualifiers or compound requests.

Qualifiers. The multivariate analysis showed a significant effect of linguistic form, $T^2 = 78.39$, $F(3, 76) = 25.46$, $p < .0001$, and a marginally significant effect of sex of speaker, $T^2 = 8.16$, $F(3, 76) = 2.65$, $p = .0541$. There was also a significant effect of sentence topic, Hotelling-Lawley trace = 1.99, F approximation $(45, 224) = 3.30$, $p < .0001$. Univariate analyses showed effects of sentence topic on all three ratings, but again no interactions (all Fs < 1). The overall effect of linguistic form was due to effects in ratings of both assertiveness and warmth. Qualified speech was seen as less assertive, with a mean rating of 5.8 as compared to 7.5 for nonqualified speech, $F(1, 78) = 60.95$, $p < .0001$, but also as warmer (mean rating of 5.5 as compared to 5.0 for nonqualified speech, $F(1, 78) = 4.71$, $p < .05$. Sex of speaker was significant in only one univariate analysis, that for assertiveness ratings, with male speakers using either qualified or unqualified speech seen as more assertive (M rating = 6.9) than females (M rating = 6.3), $F(1, 78) = 6.90$, $p \simeq .01$. That this was not due to idiosyncratic characteristics of the voices or acting of one of the speakers is suggested by the absence of any significant main effects or interactions involving identity of speaker. However, the strength of association, omega-square (Hays, 1963) of linguistic form with assertiveness ratings was .12, while the strength of association for sex of speaker with assertiveness ratings was only .01. (The strength of association for the other significant effect, sentence topic, was .09.)

Compound requests. The multivariate analysis showed significant effects of linguistic form, $T^2 = 154.78$, $F(3, 76) = 50.27$, $p < .0001$; sex of speaker, $T^2 = 11.21$, $F(3, 76) = 3.64$, $p < .05$; and identity of speaker, Hotelling-Lawley trace = .47, F approximation $(6, 150) = 5.88$, $p < .0001$. There was no significant effect of sentence topic; apparently the requests were perceived as more homogeneous than the tag question or qualifier items. Univariate analyses showed effects of linguistic form on ratings of assertiveness, $F(1, 78) = 40.14$, $p < .0001$; politeness, $F(1, 78) = 50.50$, $p < .0001$; and warmth, $F(1, 78) = 70.31$, $p < .0001$). Compound requests were rated as less assertive (M rating = 6.5 vs. 8.2 for simple requests) but more polite (6.5 vs. 4.6) and warmer (6.0 vs. 4.0). Female speakers were considered more polite than males, $F(1, 78) = 5.13$, $p < .05$, with ratings of 5.9 and 5.2, respectively. Females were also considered warmer, $F(1, 78) = 7.84$, $p < .01$, with ratings of 5.3 and 4.7, respectively. These results, however, unlike the ones for qualifiers, did seem to be due to specific characteristics of one of the two male speakers. Identity of speaker was a significant factor for ratings of both politeness and warmth, $F(2, 78) = 7.27$, $p \simeq .001$, and $F(2, 78) = 15.00$, $p \simeq .0001$, respectively. One male speaker was seen as much less polite and less warm than the other three speakers. This male received a politeness rating of 4.5, as compared to 6.0 for the second male and 5.8 and 6.0 for the two females. He received a warmth rating of 3.7, as compared to 5.6 for the second male and 5.3 and 5.4 for the two females. There was also, for the univariate analysis of the warmth ratings, a significant interaction of identity of speaker with linguistic form, $F(2, 78) = 3.34$, $p < .05$. The differences between the "cold" male speaker and the other three speakers were especially pronounced when speakers

Table 1
Judgments of Relative Frequencies of Usage of Three Linguistic Forms by Male and Female Speakers in Experiment 1

Judgment	Tag questions			Qualifiers			Compound requests		
	Males	Females	Total	Males	Females	Total	Males	Females	Total
Males use more	11	15	26	13	11	24	23	19	42
Males and females use equally	23	21	44	37	29	66	23	28	61
Females use more	42	26	68	26	22	48	20	15	35
Total	76	62	138	76	62	138	65	62	138

were using compound requests. However, the difference between the two linguistic forms appeared for all four speakers.

Frequency Estimation Data

The frequencies of usage of tags, qualifiers, and compound requests were actually equal for male and female speakers on the tape. Judgments of frequencies by all 138 subjects are shown in Table 1. (The 58 subjects discarded in the previous analyses were included here, since there was no need for an orthogonal design in this analysis.) The significance of these data was evaluated relative to a null hypothesis that subjects do not have sex stereotypes and thus judge the frequencies equal except as affected by random error due to factors such as lack of attention. Thus the null hypothesis stated that the probability of choosing *males more* would be equal to the probability of choosing *females more*. A binomial test rejected the null hypothesis of equal probability for tag questions ($z = 4.23$, $p < .001$) and for qualifiers ($z = 2.71$, $p < .01$) but not for compound requests.

The biases in frequency estimation can be interpreted either as reflecting sex stereotypes or as being accurate reports of how subjects have heard men and women talk in general, although not of how speakers talked on the experimental tape. The issue will be discussed more fully below.

Inspection of Table 1 suggests that male subjects may be more prone to bias than female subjects in making frequency judgments of tag questions, although not more prone to bias in the case of qualifiers or compound requests. However, a chi-square test carried out on the 2×3 table of responses for tag questions was not significant, $\chi^2(2) = 3.08$.

Discussion

Experiment 1 provides substantial support for several of Lakoff's intuitions regarding the effect of speech styles on person perception. Tag questions, qualifiers, and compound requests all decrease the perceived assertiveness of speech. Tags and qualifiers do not seem to increase perceived politeness, but use of qualifiers leads to higher ratings of warmth. Compound requests correspond most closely to Lakoff's hypotheses, in that their use increases ratings of both politeness and warmth as well as decreasing ratings of assertiveness.

Only one instance of an effect of sex of speaker on ratings was found in these data, that occurring for ratings of assertiveness of qualified and unqualified assertions. This effect was small relative to the corresponding effect of linguistic form: Presence or absence of a qualifier made more differences in ratings of assertiveness than did the sex of the speaker. An implication is that, when men and women do differ in frequency of usage of these three linguistic forms, the contribution to the support of sex stereotypes could be substantial. Conversely, men and women could change the way in which they are perceived by changing their speech style. However, several reservations concerning these conclusions spring to mind, perhaps most notably the fact that Experiment 1 used college students as subjects.

Perhaps an older or less well educated sample would show stronger sex stereotypes. For this reason, Experiment 2 was conducted as a replication of Experiment 1, using a different subject population.

Experiment 2

Method

Subjects

A total of 39 female secretaries employed at the university participated in return for a $2 reimbursement. Subjects were recruited through friendship networks. That is, we contacted secretaries known to us or introduced to us by a faculty member known to us and asked them to participate in the study and to bring their co-workers.

Because we wished to obtain a sample as different as possible from the undergraduates of Experiment 1, subjects were asked about their age and education, and their data were eliminated if they were under 30 years of age and had either a BA or the credit equivalent (5 people) or under 30 and had a smaller number of credits in a definite major (2 people with 52 and 100 credits). Thus data from 32 women, 4 listening to each of eight tapes, were retained. These women ranged in age from 18 to 58 years, with 7 under 20 years old, 12 aged 20–29 years, 8 aged 30–39 years, and 5 aged 40 years or over. The number of college credits they had acquired ranged from 0 to 90, with 21 having 0 and the remaining 11 having a mean of 24 credits (less than a full-year equivalent) and none having a definite major.

Stimulus Material and Design

These were as in Experiment 1, except that the design did not involve the factor of sex of subject.

Procedure

This was substantially the same as in Experiment 1, with some minor exceptions. Subjects were asked to supply information on age and education, used a computer-readable form instead of a manually scored answer sheet for making ratings, and were given money instead of extra-credit cards. They were also specifically instructed that the study had been previously conducted using undergraduates and that therefore some of the content and vocabulary of the conversation was most relevant to a college audience, for example, comments on courses, summer jobs, and living in dorms, and terms such as *frat* for *fraternity*. They were asked as far as possible to avoid considering their reactions to these "collegiate" topics or phrases in making their ratings but to concentrate on "how the speaker is coming across in general."

Results

Rating Data

As in Experiment 1, no effects of version of the tape were observed in preliminary analyses.

Tag questions. Although the multivariate analysis did not show a significant effect of linguistic form, there was a trend in the univariate analysis for tag questions to be rated less assertive than nontags, $F(1, 31) = 3.32$, $p < .10$. The mean assertiveness ratings were 6.6 for tags and 7.4 for nontags. There was again a significant effect of sentence topic, Hotelling-Lawley trace = 2.93, F approximation $(45, 83) = 1.80$, $p < .05$. Sentence topic was a significant factor in univariate analyses of warmth and politeness, but no interactions with other variables were significant. Sex of speaker did not approach significance in any analyses.

Qualifiers. The multivariate analysis showed a significant effect of linguistic form, $T^2 = 11.99$, $F(3, 29) = 3.74$, $p < .05$. Qualified speech was seen as less assertive ($M = 6.4$) than nonqualified speech ($M = 7.6$), $F(1, 31) = 8.23$, $p < .01$, although not as warmer, as it had been in Experiment 1. Neither sentence topic nor sex of speaker was a significant effect.

Compound requests. The only significant effect in the multivariate analysis was that of linguistic form, $T^2 = 35.92$, $F(3, 29) = 11.20$, $p < .0001$. Compound requests were rated less assertive than simple requests (7.2 vs. 8.5) but also warmer (6.6 vs. 4.6) and more polite (6.7 vs. 5.2). In the univariate analyses corresponding to these comparisons, $F(1, 31) = 14.93$, $p < .001$; $F(1, 31) = 16.28$, $p < .001$; and $F(1, 31) = 8.14$, $p < .01$. The univariate analysis of the warmth ratings showed a trend to an effect of sex of speaker, $F(1, 31) = 3.48$, $p < .10$, but as in Experiment 1, this was qualified by a trend to an identity of speaker effect, $F(2, 31) = 2.93$, $p < .10$. Inspection of means again showed that one male speaker was rated less warm than the other male, who was comparable to the two females.

Comparison with Experiment 1. A quanti-

tative assessment of the apparent similarity between Experiments 1 and 2 was undertaken by analyzing both studies together, including the experiment number as an independent variable with two levels and including all interactions between the experiment variable and the other independent variables. Male subjects from Experiment 1 were not included in the analysis, and 1 female subject was randomly dropped from each version of Experiment 1, so that both experiments would be equally weighted in the analysis (32 female subjects in each experiment).

For tag questions and qualifiers, multivariate analyses of variance showed no significant main effects of experiments. The analysis for compound requests did produce a marginally significant main effect, $T^2 = 8.27$, $F(3, 61) = 2.67$, $p = .0545$. Univariate analyses indicated that the secretaries in Experiment 2 gave speakers higher warmth ratings than did the female students in Experiment 1, $F(1, 63) = 4.28$, $p < .05$, and tended to give higher assertiveness ratings, $F(1, 63) = 3.39$, $p < .10$. However, no significant interactions involving the experiment variable were found in any of the three multivariate analyses. Thus the findings do not depend on which subject population is being considered.

Frequency Estimation Data

Judgments of the frequencies with which male and female speakers used tag questions, qualifiers, and compound requests are shown in Table 2. There is, again, no bias in estimations for compound requests. There are tendencies to biases in estimations for tag questions and qualifiers, although the tendency is not very marked for tag questions, and binomial tests are not significant in either case.

Discussion

Experiment 2 substantially replicated the effects of linguistic form obtained in Experiment 1, despite the reduction in power due to the reduction in sample size. No hint was obtained that sex of speaker was a significant factor for this subject population. Thus, the idea that an older or less well educated sample would have stronger sex stereotypes than the undergraduates and would thus rate male and female speakers very differently was not supported.

Table 2
Judgments of Relative Frequencies of Usage of Three Linguistic Forms by Male and Female Speakers in Experiment 2

Judgment	Tag questions	Qualifiers	Compound requests
Males use more	8	5	8
Males and females use equally	13	17	16
Females use more	11	10	8
Total	32	32	32

General Discussion

The results of these two studies indicate that as Lakoff has suggested, variations in the use of tag questions, qualifiers, and compound request forms can affect how people are perceived. The sex of the speaker had small and largely nonsignificant effects on ratings. However, before concluding that sex differences in speech style could contribute to the support of sex stereotypes and that changes in speech style might allow men and women to modify how they are perceived, we should consider the fact that the frequency estimation data from both studies can be interpreted as demonstrating the existence of sex stereotypes. Subjects are probably aware that they have been rating tag questions and qualified speech as less assertive than declaratives. They may therefore guess that the female speakers use these forms more frequently because they have a stereotype of women as less assertive than men.

This way of accounting for the frequency estimation data implies a contrast between behavior in specific situations with specific individuals (i.e., rating the speech of a particular speaker on a particular topic) and behavior in more abstract situations involving thought about a class of individuals (i.e., the reasoning outlined above for the frequency

estimation task). Judgments about concrete instances of behavior may be less influenced by sex stereotypes than judgments regarding a general class of behaviors. A woman speaking in a direct and self-confident style might thus be seen as self-confident, but the same individuals who saw her this way might still maintain that women in general are not very confident and do not speak assertively. However, the cumulative impact of judgments of the self-confidence of individual women might be to change general stereotypes.

There is, however, an alternate interpretation of the distortion in frequency estimation. In guessing about frequencies of use on the tape, subjects may unconsciously average speech they have heard in real-world contexts, rather than considering only the experimental tape. Of course, if this second idea is correct and frequency estimations reflect unconscious averaging of speech heard by subjects outside the experiment, the interpretation of the data from the experiment as a whole is more straightforward. Men and women do speak differently, at least in certain contexts, in ways that affect how they are perceived. Changing one's speech style could potentially change these perceptions.

An important question in discussing sex-related variation in speech styles has been whether the important dimension governing choice of speech style may be status rather than sex. Thus, it has sometimes been suggested that "female speech style" is really the language of the powerless or the lower in status rather than the language of women, and that women high in status or power do not use female speech style, although low-status men do use this style (Dubois & Crouch, 1975; Erickson et al., 1978; Key, 1972; O'Barr & Atkins, in press). Other sociolinguistic work, for instance that of Ervin-Tripp (1976) on imperatives, supports the idea that status differences result in linguistic variation of a kind similar to that claimed by Lakoff to be a function of sex.

Lakoff (1977) disputes the "language of the powerless" idea and claims that women with power still speak in female style, that some men with power (i.e., academics and artistic–literary men) also speak this way, and that minorities (e.g., blacks) who lack power do not speak this way. Crosby and Nyquist's (1977) finding that role and sex both condition the use of "female register" but do not interact partially supports Lakoff's argument. Status (or role) does make a difference, but within roles, females differ from males.

While empirical work is necessary to evaluate these claims and resolve the issue, it may be helpful to clarify the question being asked by contrasting two views of the relationship of sex and status to linguistic variation. A straightforward "status" hypothesis claims that, while sex and status are confounded in the real world, all speakers control all forms and can switch easily and flexibly as a function of a particular status situation. Conversely, listeners expect such context-based variation and are comfortable with it; the sex of the person holding a particular status position is irrelevant. A contrasting view holds that the real-world correlation of sex and status results in relatively stable speech patterns and listener expectations not so easily changed as a function of situation. These might result in part from early socialization, since mothers and fathers and male and female day-care teachers model sex-differentiated language in speech to preschoolers (Gleason & Weintraub, 1978) and since work on imperatives suggests that situation-based variation in commanding and requesting is well established at least by 4½ or 5 years of age (James, Note 2) and perhaps as early as 2½ or 3 years (Bates, 1976; Ervin-Tripp, 1976, 1977; Newcombe & Zaslow, Note 3). How early one's own sex is used as a basis for choosing linguistic forms is not known, however. The ability to use linguistic cues to *infer* sex of speaker undergoes considerable change during the elementary school years (Edelsky, 1977). If speech patterns and listener expectations are relatively stable, high-status women might well be in the double bind described by Lakoff (1975): branded unfeminine and unlikeable if they adopt male style and vague and frivolous if they adopt female style.

Effects of Resource Availability and Importance of Behavior on the Experience of Crowding

Richard McCallum, Caryl E. Rusbult, George K. Hong,
University of North Carolina, Chapel Hill

Tedra A. Walden
University of Florida

John Schopler
University of North Carolina, Chapel Hill

According to the interference formulation, participants in a crowded setting will experience interference to the extent that behavioral goals conflict with environmental conditions. The importance of the behavioral goals directly affects not only the magnitude of the interference but also the mechanism by which people cope with interference. It was reasoned that important goals would induce a more active coping strategy in a crowded setting than in an uncrowded setting and would maintain task performance at the price of increasing crowding stress. When the behavioral goal is unimportant, decrements in task performance preclude a rise in stress. A laboratory study manipulated group size, in order to vary the availability of resources, and the importance of the task behavior. The predictions were confirmed, and partial confirmation was obtained for predictions involving the effects of the internal–external personality dimension. The meaning of the results is discussed in terms of other findings in the literature on crowding and the mediating role of the type of mechanism used to cope with interference.

A number of variables have been said to mediate between conditions of high physical density and the experiences of subjective crowding and crowding stress. The variables include excessive stimulation from social sources (Desor, 1972), excessive and unwanted social interactions (Valins & Baum, 1973), restricted behavioral choice (Proshansky, Ittelson, & Rivlin, 1972), decreased interaction distance (Worchel & Teddlie, 1976), and breakdowns in privacy-regulating mechanisms (Altman, 1975). In an attempt to subsume these mediating factors under a single generic variable, Schopler and Stockdale (1977) suggested that interference with goal-directed behavior sequences is the crucial mediator between density and the experience of crowding stress.

The behavioral interference formulation is a sequential model that views physical density as a necessary but not sufficient condition for the occurrence of crowding stress. When the presence of other people in large numbers or in close physical proximity leads to interference with goal-directed behavior, stress is experienced. The degree of stress experienced in a given setting is determined by several factors that affect the impact of interference produced in the setting. These include the anticipated duration of the interference, the importance of the vulnerable response sequences, and personality factors related to anticipated control. This framework accounts for interference in terms of the reward–cost ratio associated with particular behaviors in a given setting. The effect of density-induced interference is to increase the costs of enacting the desired behavioral sequences. This increased cost may be manifested in various forms, such as annoyance, embarrassment, anxiety, or increased effort for making appropriate responses. Implicit in this formulation is the assumption that crowding stress is jointly determined by the physical and social

characteristics of the setting and the nature of the behavioral goals set by the actor. Interference is experienced to the extent that behavioral goals conflict with environmental conditions.

Schopler, McCallum, and Rusbult (Note 1) provided evidence for the relationship between behavioral interference and the subjective experience of crowding. Subjects in this study worked on a group decision task under conditions of either high or low density. This factor was crossed with a manipulation that imposed structure on the interactions of half of the groups. The imposition of structure reduced the potential for interference in the high-density setting by providing for the coordination and synchronization of responses among group members. Consistent with the interference model, subjects in the high-density conditions perceived less interference and reported less subjective crowding with the imposition of structure. Similar results have been reported by Baum and Koman (1976). These investigators manipulated anticipated group size and found that subjects expecting to meet with a large group felt less crowded when anticipating structured interactions than when no structure was expected.

The present experiment was designed to test the interference model prediction regarding the relationship between crowding stress and the importance to the actor of vulnerable response sequences. One direct way in which high-density settings produce interference with goal-directed behaviors is to place limitations on access to available resources. The term *resource* refers to those features of the physical/social environment that are necessary for the attainment of behavioral goals. In natural settings, resources may include doorways, seating, clear lines of vision or movement, physical or verbal access to others, adequate materials for task completion, and so forth. The designation of a given environmental feature as a *resource* requires specification of the particular behaviors enacted in the setting. Consequently, the setting features required as resources will vary not only from setting to setting but also across individuals within the same setting and across time for a given individual. Despite these potential variations, it is evident that conditions of resource scarcity should produce interference and consequent stress.[1] The first hypothesis of the present study was merely that individuals provided with inadequate resources to complete required tasks would report greater subjective crowding and crowding stress and would perform less well than individuals provided with sufficient resources. This hypothesis is consistent with many points of view, including the interference formulation. Predictions regarding the effects of resource availability and importance upon actual task performance and crowding stress, however, do stem directly from the interference formulation. These effects depend upon the strategy the participants select to cope with interference and their success in maintaining task performance. It is useful to distinguish two general coping strategies for dealing with interference in high-density settings. One strategy involves active intervention of the type required for coordination and synchronization of responses, whereas another involves passive withdrawal from interaction, altering behavioral goals, and lowering expectations (Thibaut & Kelley, 1959). Either of these general strategies may be successful in reducing the degree of conflict between behavioral goals and environmental conditions and may consequently reduce crowding stress. To the extent that the behavioral sequences to be enacted in a setting are important to the individual, however, passive withdrawal and lowered expectations should become less attractive as coping strategies. A second prediction was that given low importance, the scarce-resources condition would evidence a performance decrement relative to the adequate-resources condition. The average effect

[1] The availability of resources may be manipulated in an experimental paradigm by holding group size constant and varying resources or by holding resources constant and varying the number of people who must compete for them. Group size was manipulated in the present experiment. Because the functional importance of group size, in our experimental setting, was in relation to the availability of task resources, we have labeled the manipulation *resource availability* throughout the article, rather than *group size* or *density*.

of resource availability upon task performance predicted by Hypothesis 1 is therefore modified by the interaction contrasts described by Hypothesis 2.

The interference formulation predicts that crowding stress increases in magnitude with increases in the importance of vulnerable response sequences. This effect of course assumes that the conditions expected by Hypothesis 2 will pertain, that is, that raising the importance of the goal will induce an active coping strategy even in the face of high interference. Under these restricted conditions, variations in resource availability should have an effect when behavioral goals are important but not when behavioral goals are unimportant. Specifically, among individuals working for important goals, subjects given inadequate resources should experience more crowding stress than should subjects given adequate resources. In contrast, individuals working for unimportant goals should be less affected by variations in resource availability. The average effect of resource scarcity upon crowding stress predicted by Hypothesis 1 is therefore modified by the interaction contrasts described by Hypothesis 3.

In addition to variables associated with the setting characteristics and the nature of the participants' behavioral goals, the present experiment investigated the effect of a personality variable that is conceptually related to the interference analysis. Stockdale (1978) has emphasized the importance of the perception of environmental control in determining the degree of actual or anticipated interference experienced in high-density settings. To the extent that the potential for exerting control over the social environment (through coordination and synchronization of behaviors) is salient to participants, the negative effects of interference on subjective crowding and crowding stress should be mitigated. Individuals who typically anticipate a high degree of personal control in social situations should therefore experience fewer negative effects of density-induced interference. A scale designed to assess individual expectancy of internal or external control over the social environment (Schopler, Langmeyer, Stokols, & Reisman, 1973) was employed to locate subjects on this personality dimension. The fourth hypothesis was that within the scarce-resources (high interference) condition, individuals identified as externals should experience greater crowding and crowding stress than should internals. No internality–externality differences in subjective crowding and crowding stress were predicted within the adequate-resources condition because the existence of adequate resources should obviate the salience of control considerations. Such results would be consistent with the findings that externals report more subjective crowding under high-interference conditions and respond more favorably than do internals to manipulations designed to reduce interference experienced in high-density situations (Schopler, McCallum, & Rusbult, Note 1). These results parallel the findings of research that directly manipulated perceived control. For example, Glass and Singer (1972) found fewer behavioral effects and aftereffects of another environmental stressor (noise) when subjects believed they controlled the onset of the aversive stimulus, and Sherrod (1974) demonstrated that subjects who controlled when they could leave a crowded setting showed greater tolerance for frustration on a postcrowding task.

Because the interference formulation and many other conceptions of crowding speculate about the arousal and reduction of crowding stress, identification of an adequate measure of this kind of stress is of general importance. The obvious limitations of self-reports of stress, among other considerations, have led some investigators to seek physiological indices. Although it is by no means evident that a variable as complex as crowding stress will have a reliable physiological counterpart, the literature contains some suggestions, such as the Palmar Sweat Index (PSI; Johnson & Dabbs, 1967) or blood pressure (D'Atri, 1975). We undertook to explore the adequacy of PSI as a measure of crowding stress in the present study.

Method

Subjects

Seventy-two males and 72 females participated in the experiment in partial fulfillment of the re-

quirements for an introductory psychology course. Subjects were assigned to 16 same-sex six-person and 16 same-sex three-person groups. Four six-person and four three-person groups of each sex were randomly assigned to two importance conditions.

Procedure

The study employed four independent variables in a complete $2 \times 2 \times 2 \times 2$ factorial design: availability of resources (scarce or adequate), importance of behavior (high or low), locus of control (internal or external subject orientation), and sex of subject.

Upon arrival at the laboratory, subjects were escorted to a waiting room by one experimenter who was of the same sex as the subjects and were given numbered clipboards. (Two women and two men served as experimenters for the study.) The experimenter briefly described the procedure as a simulation of working conditions in a large business organization. The subjects were told that they would be asked to perform clerical work under controlled conditions so that factors affecting work quality and job satisfaction could be evaluated. Subjects wishing to terminate participation in the experiment without penalty were given the opportunity to do so at this point. The experimenter then administered the North Carolina Internal–External Scale (Schopler et al., 1973). Instead of categorizing individuals relative to the sample median, locus of control assignments were determined for each subject on the basis of the standardization mean (if his/her score was 72 or lower, the subject was assigned internal status, and if his/her score was 73 or higher, the subject was assigned external status).

In order to obtain a measure of physiological stress (the Palmar Sweat Index) without arousing subject suspicion as to its purpose, the experimenter requested the subjects' cooperation in helping another graduate student (the second experimenter present at the session) pretest for an experiment he/she was preparing to run. The second experimenter stated that he/she wanted to pilot test a measure of concentration called the "PCI" and explained that in order to assess the stability of the measure across various activity levels, several measures would be obtained throughout the experimental session. The PSI was obtained by painting a special chemical on the fingertip and transferring the print to a slide with a piece of transparent tape. After demonstrating the administration of the PSI on the primary experimenter, the second experimenter obtained a baseline palmar sweat measure from each subject.

The primary experimenter then accompanied the group to a mock office containing six (or three) chairs placed in a semicircle facing three standard four-drawer file cabinets. Subjects were instructed to occupy the chair that corresponded to their respective clipboard numbers. Availability of resources was manipulated by variations in the size of the group. The resources available for work on the task (such as physical space and equipment) remained constant across all conditions. The mock office itself measured 2.86 m by 4.11 m and contained the subjects' chairs as well as the three file cabinets placed against one wall and spaced 60 cm apart. While these resources were sufficient for three-person groups, they were insufficient when divided among the members of larger groups. That is, while members of smaller groups seldom experienced difficulty in obtaining access to the files, resources were insufficient and led to problems of interference and a greater need for coordination of behaviors in the larger groups.

The experimenter distributed a different list of names to each subject and explained the experimental task. The file cabinets contained a set of alphabetically ordered folders, and the subjects' task was to locate the file for each name on their lists and to record the home address listed for each of those names. Subjects were told that they would receive "credit" for names only if their records of each address corresponded exactly to that on the experimenter's master list. Subjects were also asked to complete the names in the order in which they appeared on the lists.

Subjects in the low-importance condition were instructed to work as quickly and as carefully as possible and were told that individuals were typically able to complete from 20 to 60 names during the experiment. The other half of the subjects, those in the high-importance condition, were told that in order to simulate piecework schedules they would be paid 15 cents for each name they located and correctly identified. These subjects were informed that typical earnings in the experiment ranged from \$2 to \$8, the average being about \$5. The offer of monetary incentives contingent on high quality and quantity performance was intended to increase the relative importance of task-related behaviors.

After 5 minutes subjects' task work was interrupted to obtain a second PSI reading from each subject. Subjects then resumed work for an additional 5 minutes, after which the primary experimenter administered the experimental questionnaire. Subjects were then informed that the task work was completed, were escorted back to the waiting room, and were thoroughly debriefed. Subjects in the high-importance condition were paid \$5 each for participation in the experiment (this amount was greater than that actually earned by any subject).

Dependent Variables

The experimental dependent variables comprised four separate conceptual groupings. The first group was designed to measure crowding stress and included ratings of subjects' reported stress, per-

sonal feelings, attitudes toward other group members, and intentions concerning task performance. The second set consisted of measures of subjective crowding, whereas the third and fourth sets consisted of single measures—task performance and Palmar Sweat Index, respectively. Items were also included to evaluate the effectiveness of the manipulations of availability of resources and importance of the behavior.

Nine items were included in the crowding stress group. Affective reactions were assessed by requiring the subjects to rate both their "normal" feelings and their feelings during the experiment on four pairs of 9-point semantic differentials (pleasant–unpleasant, cooperative–uncooperative, nervous–calm, friendly–unfriendly). These ratings were then converted to difference scores (experimental rating less normal rating) to facilitate statistical analyses. Subjects also rated the degree to which the experience of working in the experimental setting was stressful, the extent to which task work was distressing compared to the subject's experience during a typical day, the extent to which their expectations concerning task performance decreased during work on the task, the difficulty of coordination with other group members, and the extent to which others interfered with task work.

Subjective crowding was assessed by six 9-point bipolar scales. These items asked: "Is there (too much – too little) room for you to work on the task?" "To what extent do you feel (extremely crowded – extremely uncrowded) by the other group members?" "Is there (too much – too little) room for you to feel comfortable while working on the experimental task?" "Do you feel (extremely unconfined – extremely confined) physically while working on the task?" "Do working conditions in this room make task work (much harder – much easier)?" "To what extent is the experimental room (congested – uncongested)?"

Task performance was evaluated by simply counting the number of items correctly completed by each subject. A baseline and task-related PSI score was computed for each subject. Two raters ignorant of the experimental conditions scored the PSI measure by counting the number of open sweat pores within a standard 4-mm square area for both the baseline and the task-related measures. Scores of the two raters were reliable and yielded a correlation of .97.

Two 9-point bipolar scales assessed the effectiveness of the availability-of-resources manipulation and required that subjects estimate the extent to which they would have performed better had they been alone in the room and indicate whether there were too many people in the room.

Four 9-point bipolar scales assessed the effectiveness of the manipulation of the importance of the behavior. These measured liking for the task, importance of task performance, difficulty of the task, and amount of effort expended on task work.

Results

Manipulation Checks

Except where otherwise indicated, the individual responses on each dependent measure were averaged and the group mean employed as the unit of analysis, avoiding problems associated with possible response dependence within experimental groups. To assess the effectiveness of the availability-of-resources manipulation, a two-factor analysis of variance was performed on the measures associated with this factor. Subjects in the large groups were more likely than those in small groups to report that they would have performed better had they been alone in the room and that there were too many people in the room. The means on the ability-to-perform measure were 8.07 for the scarce-resources condition and 7.44 for the normal-resources condition, and the respective means for the number-of-people measure were 7.20 and 6.23, multivariate $F(2, 27) = 16.92$, $p < .001$. Thus it appears that the manipulation of availability of resources was successful.

The success of the importance-of-behavior manipulation was assessed by four items designed to measure subjects' reactions to the experimental task. Subjects in the high-importance condition reported greater liking for the task, stated that it was more important for them to perform well on the task, perceived task work as more difficult, and estimated that they had expended greater effort on task work than did subjects in the low-importance condition. A two-factor analysis of variance revealed that the difference between the two conditions on these measures was only marginally significant, multivariate $F(4, 25) = 2.31$, $p < .086$. Although the importance manipulation was judged satisfactory, the marginal significance of the mean differences should be recalled in evaluating the results of the experiment.

Tests of the Major Hypotheses

Initial analyses revealed that no significant effects were obtained with the nervous–calm and friendly–unfriendly measures, and these

Table 1
Mean Values of all Dependent Measures as a Function of Importance of Behavior and Resource Availability

Item	Importance of behavior			
	High		Low	
	Scarce resources	Adequate resources	Scarce resources	Adequate resources
Behavior

variables were not considered further. Although no experimental hypotheses were advanced with respect to sex of subject, the influence of this factor was examined in order to assess the universality of the experimental results. A three-factor analysis of variance was performed on each of the four sets of dependent variables. There were no significant multivariate main effects nor interactions associated with sex of subject, and this factor was not included in the remaining analyses.

The first experimental hypothesis predicted that scarce resources would produce greater subjective crowding, crowding stress, and task decrements than would adequate resources. A two-factor analysis of variance revealed a significant effect of resource availability on participants' subjective crowding, multivariate $F(6, 23) = 9.90$, $p < .001$; crowding stress, multivariate $F(7, 22) = 2.48$, $p < .05$; and task performance, $F(1, 28) = 8.66$, $p < .006$. Participants in the scarce-resources condition reported greater subjective crowding and greater crowding stress and performed less well on the experimental task than did participants in the adequate-resources condition. The resource-availability manipulation did not significantly affect participants' physiological reactions to the setting (as measured by the PSI score, covarying initial PSI levels). The significant effects, in essence, confirm that the resource-availability manipulation established the circumstances required to test the hypotheses involving importance. Induction of scarce resources by an increase in group size did create the required crowding and interference with actual task performance. The lack of an effect for PSI scores precluded consideration of this measure. We will return to this regrettable fact in the discussion.

Hypotheses 2 and 3, stated as planned comparisons, were tested by a series of simple effects analyses because standard analysis of variance does not provide the specific contrasts necessary to test the hypotheses. It is

necessary to examine the influence of variations in availability of resources within both the high-importance and the low-importance conditions. It will be recalled that the second hypothesis expected high, but not low, importance to maintain task performance in the face of scarce resources. Consistent with the experimental hypothesis, scarcity of resources significantly affected performance among low-importance subjects, $F(1, 28) = 6.57$, $p < .02$, but did not significantly influence performance in the high-importance condition, $F(1, 28) = 2.56$, $p < .12$. Average performance scores are shown in Table 1. It is apparent that subjects in the high-importance condition produced a uniformly high level of performance (these subjects averaged 16.16 completed items per session), whereas subjects in the low-importance condition responded to variations in availability of resources. Within the low-importance condition, scarce-resources subjects averaged 14.4 completed items, whereas adequate resources subjects averaged 16.8 items. When motivated by the potential for monetary gain, subjects overcame the interference created by scarce resources and performed at a high level of productivity. When task behaviors were of relatively low importance, however, variations in availability of resources produced commensurate decrements in task performance.

In accord with the interference formulation, Hypothesis 3 predicted that subjects' crowding stress would be adversely affected by scarcity of resources when the task behavior was of high importance to the subject but not when it was of low importance. In support of this prediction, the crowding stress measures were influenced by variations in availability of resources within the high-importance condition, multivariate $F(7, 22) = 2.40$, $p < .05$, but not in the low-importance condition, multivariate $F(7, 22) = 1.62$, $p < .18$. Mean responses on these dependent variables are presented in Table 1, where it can be seen that for the seven stress items, only two (*distress* and *others interfere*) do not show the predicted pattern. With hindsight, these two items appear to be deficient in tapping events that were not strictly task related.

Locus of Control

It was predicted that among scarce-resources subjects in the high- and low-importance conditions, the stress responses, subjective crowding, and physiological reactions of external subjects would be more negative than those of internal subjects. This hypothesis was tested by simple effects analyses and was by necessity performed using the individual rather than the group as the unit of analysis. It should be noted that the use of locus of control as an independent variable produced a nonorthogonal experimental design. The reader is referred to Appelbaum and Cramer (1974) for a description of the series of ignoring and eliminating procedures that were employed to produce accurate tests of significance.

Analysis of subjects' stress responses indicated that externals reported more negative affect than did internals in the high-importance scarce-resources condition, multivariate $F(7, 130) = 2.11$, $p < .05$, but within the low-importance scarce-resources condition, internality–externality did not have the predicted effect, multivariate $F(7, 130) = 1.15$, $p < .34$. As expected, internality–externality did not significantly influence affective responses within the adequate-resources condition.

A similar pattern of results was obtained for the measures of subjects' subjective crowding. Among scarce-resources subjects, externals consistently responded more negatively than did internals, but the effect for internality–externality within the high-importance scarce-resources condition is significant, multivariate $F(6, 131) = 2.33$, $p < .04$, whereas the internality–externality effect within the low-importance scarce-resources condition was not significant, multivariate $F(6, 131) = 0.21$, $p < .98$. Again, internality–externality had no significant effect on subjects' responses in the adequate-resources condition.

There were no locus-of-control main effects nor interactions on the measures of performance or physiological stress.

Discussion

The major focus of the present research was to evaluate the effects of varying the importance of the behaviors vulnerable to interference by others. We successfully induced crowding and interference through the creation of scarce resources by manipulating group size. Individuals working in the scarce-resources condition, compared to those working in the adequate-resources condition, reported more crowding and crowding stress and completed fewer items on the task. These effects are hardly remarkable, although they do underscore the reason why some experiments, for example, those of Freedman, Klevansky, & Ehrlich (1971), find no performance decrements with high density, whereas other experiments, such as ours or that of Heller, Groff, & Solomon (1977), do find performance decrements. The difference appears to reside in whether or not the crowding manipulation and the particular task used intersect to produce scarce task resources and interference. Freedman, Klevansky, and Ehrlich used problem-solving tasks and manipulated room size, a combination that was selected explicitly to minimize task interference by unhinging high density from scarce resources. In our experiment and that of Heller, Groff, and Solomon, a performance task was combined with the heightening of density by increasing group size. This combination produces task interference and performance decrements.

Based on the interference model (Schopler & Stockdale, 1977), it was predicted that the aversive impact of interference would be greater when behaviors encountering interference are important to the actor. The second and third hypotheses expected efforts to maintain task performance, when the goal was important and despite scarce resources, by an active coping strategy that also produced increased stress. The data confirmed these predictions for task performance and for stress. Subjects responded more negatively to scarce resources on the stress measures only when they were provided with incentives to perform well on the task. In accord with the interference analysis, subjects who were highly motivated to complete goal-directed behavior sequences experienced more psychological costs than did less motivated subjects when these behaviors encountered interference from the physical/social environment. These results suggest that in understanding the impact of high-density settings, specifying the nature and importance of behaviors enacted in these settings is as necessary as specifying the nature of the settings themselves.

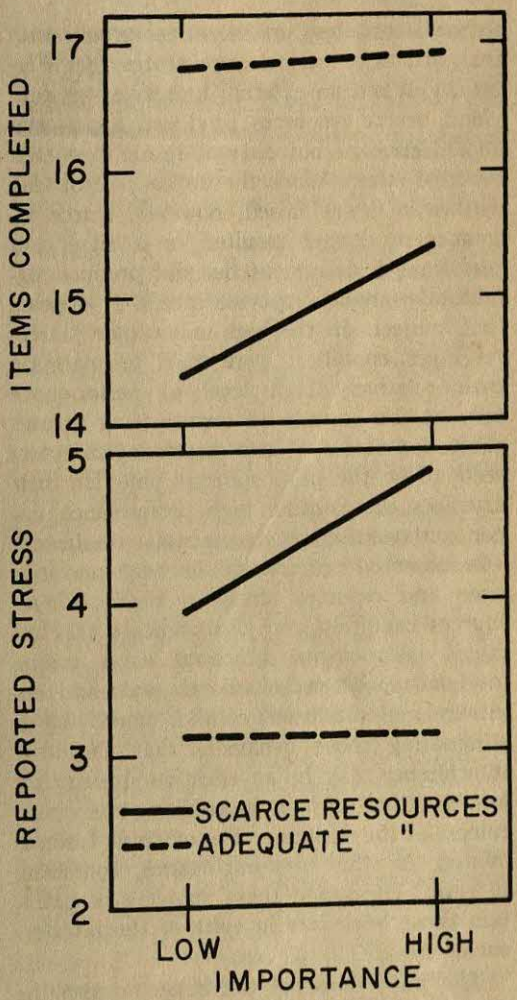

Figure 1. Mean number of items completed and reported stress as a function of resource availability and level of importance.

Further evidence of the relationship between reported stress and the interference produced by high-density settings is revealed in a comparison of the pattern of responses

to the stress item, in the stress group, with the pattern of performance scores (see Figure 1). When no external incentive was provided, scarce resources produced a performance decrement but did not result in greater reported stress. When the importance of task performance was raised, however, scarce resources no longer resulted in a significant performance decrement but did produce significantly greater reported stress. It appears that subjects in the high-importance scarce-resources condition were able to maintain their relatively high level of performance only at the expense of experiencing greater subjective stress. These psychological costs seem to be the price subjects paid for their attempts to maintain high performance under unfavorable environmental conditions. The observed relationship between performance and reported stress in the scarce-resources condition may also indicate that reduced task output functions as a coping mechanism. When behavioral goals and environmental conditions conflict, modifying or eliminating those behaviors that encounter interference may be an effective strategy for low-incentive subjects in reducing the stressfulness of the situation. The extrinsic rewards offered in the high-importance condition, however, encourage these subjects to maintain those behaviors in spite of the interference.

The importance of the behavior and the scarcity of task resources may also be the critical features determining when crowding and sex of subject interact with respect to affective feelings. Increases in density have raised positive feelings for women while lowering them for men, both when the measures are taken in the crowded situation (Freedman, Levy, Buchanan, & Price, 1972; Ross, Layton, Erickson, & Schopler, 1973) and when they are taken after the participants have left the crowded situation (Epstein & Karlin, 1975). Affective ratings are included in our crowding stress group. It will be recalled that we found no interactions with sex of subject on these measures. We would suggest that the sex interaction effect will not occur when the mechanism used to cope with interference does not lower crowding stress. The cohesion and cooperativeness that characterizes groups of women, according to Epstein and Karlin, will probably not survive the combination of scarce resources and high importance.

Although it was predicted that externals would respond more negatively to the scarce resources present in the large group under both high and low importance, this effect was observed only in the high-importance condition. A possible explanation of this result is suggested by reference to our previous discussion regarding the most likely coping strategies in the high- and low-importance conditions. A passive withdrawal strategy, resulting in reduced performance, may seem equally attractive to internals and externals when incentive is low. The high-importance condition favors internals because it requires a more active strategy aimed at coordinating and synchronizing responses to keep performance high. Thus, individual differences in expectancies for control over the social environment produce differing affective responses when the desirable coping strategy requires active intervention.

No significant effects were obtained for the physiological measure of stress. One of the problems with attempting physiological measures in crowding studies is the disrupting and distracting influence of the measurement process itself. The PSI was selected for use because it allowed subjects the necessary mobility and could be administered relatively quickly. To further reduce the disruptions inherent in taking the measure, the PSI was administered only twice. The data, which reflect generally higher scores on the initial administration, suggest that a longer baseline period with several administrations would have been desirable. The longer baseline period would allow subjects an opportunity to adapt to the measurement procedure itself and might have resulted in a greater sensitivity to the experimental manipulations. However, the nonsignificant results for the PSI must also lead us to entertain the possibility that physiological stress does not in actuality adhere to the pattern obtained for self-reported stress and negative affect. This seems plausible in view of the relatively brief

duration of the experimental session. In any case, we feel that the development of a sensitive and easily administered measure of physiological stress would add much to a literature that has relied heavily on self-report measures.

The results of this study have been interpreted in support of the interference model of crowding. This model locates the aversive impact of high-density settings in the increased costs of enacting behaviors when environmental conditions are in opposition to the actor's behavioral goals. Aversive psychological consequences were shown to be a joint function of the degree of density-related interference and the importance to the actor of his or her goal-directed behaviors. The relationship between density and actual task performance was also qualified by the importance of the task-related behaviors. When highly motivated individuals are successful in maintaining high levels of performance under high-density conditions, the increased costs of enacting the necessary behaviors are reflected in their negative affective responses to the situation.

Identifying Victims of Groupthink From Public Statements of Decision Makers

Philip E. Tetlock
Yale University

The present study attempts to test hypotheses derived from Janis's groupthink analysis of several foreign policy decisions of the American government. Content analyses were performed using the public statements of key decision makers involved in crises for which Janis's case studies revealed or did not reveal evidence of groupthink. Consistent with Janis's theory, it was found that, relative to non-groupthink decision makers, groupthink decision makers were more simplistic in their perceptions of policy issues and made more positive references to the United States and its allies (own group). Inconsistent with Janis's theory, groupthink decision makers did not make significantly more negative references to Communist states and their allies (opponents). Possible explanations for the findings are assessed, and methodological and practical obstacles to definitive testing of the groupthink model are examined.

Investigators have taken diverse theoretical approaches to the problem of how psychological factors influence political decision making. Most of this research has focused upon psychological processes that occur within individuals: unresolved psychodynamic conflicts (e.g., Glad, 1973); the needs for achievement, affiliation, and power (Winter, 1973); cognitive maps of the political world (e.g., Abelson, 1973; Axelrod, 1976; Holsti, 1976; Jervis, 1976); pressures toward cognitive consistency (e.g., Jervis, 1976); or the effects of stress on information processing complexity (e.g., Hermann, 1972; Suedfeld & Tetlock, 1977).

Political decisions are not, of course, made in a social vacuum. They are usually made in organized group contexts in which implicit and explicit norms regulate the conduct of the decision maker. However, relatively few psychologically oriented studies have considered how patterns of social interaction among policy makers can influence decision making. One noteworthy exception to this generalization is the work of Janis (1972) on the *groupthink* phenomenon. Janis argued that intense social pressures toward uniformity and in-group loyalty within decision-making groups can build to the point where they seriously interfere with both cognitive efficiency and moral judgment. Groupthink occurs when independent critical analysis of the problem facing the group assumes second place to group members' motivation to maintain group solidarity and to avoid creating disunity by expressing unpopular doubts or opinions.

In several case studies of major foreign policy decisions by the American government, Janis attempted to trace the effects of social pressures toward groupthink on decision making. He selected for analysis cases in which he felt the signs of poor decision making as a result of concurrence seeking were "unmistakable" (Janis, 1972, p. 10). These included the decisions to pursue the

The author is very grateful to the many individuals without whose help this research would have been impossible. Professors Irving Janis and Peter Suedfeld provided many extremely useful suggestions throughout the project. I have also received invaluable practical assistance from Terry Murray, Elizabeth Ballard, and Ariel Levi, among others.

defeated North Korean army beyond the 38th parallel, to launch the Bay of Pigs invasion of Cuba, and to escalate involvement in the Vietnam War. In each situation, Janis discovered similar predisposing conditions to groupthink. The policy makers invariably belonged to cohesive groups characterized by high levels of mutual attraction among the members. The policy-making groups were relatively insulated from the judgments of qualified outsiders and lacked systematic procedures for evaluating and searching out new evidence relating to the problem. During the deliberations on the particular issues, the group leaders tended to promote their preferred solutions rather than to encourage open-minded, careful analysis of policy alternatives. Finally, all decisions were made in highly stressful situations in which policy makers were not hopeful of finding an alternative superior to the one that the group currently favored.

Under these conditions, certain distinctive attitudes and patterns of interaction emerged within the groups (see Janis, 1972, pp. 197–198). Decision makers appeared to believe that the group was invulnerable to outside attack—a belief that encouraged excessive optimism and risktaking. Group members undertook collective efforts to discount warnings concerning the popularly agreed-upon solution and exhibited unquestioning belief in the inherent righteousness of the group's policies and the inherent immorality and incompetence of the enemy. Decision makers often self-censored any personal doubts about the group's policies. The group applied direct pressure to those few members who showed signs of deviating from the consensus. Self-appointed "mindguards" shielded the group from external sources of dissonant or counterattitudinal information.

In a social atmosphere so inhospitable to rigorous analysis of policy options, decision-making procedures fell far short of the ideal "rational actor" standard (cf. Allison, 1971). According to Janis and Mann (1977), decision making in groupthink situations failed to meet any of the major procedural criteria that they used to determine whether decision-making procedures were of high quality. Groupthink policy makers generally did not (a) adequately survey the full range of policy alternatives; (b) consider the full spectrum of objectives that might be affected by the chosen policy; (c) obtain adequate information for evaluating the alternative policies; (d) weigh the costs and benefits of each alternative carefully; (e) take proper account of information that contradicted prior beliefs and preferences; (f) reexamine evaluations of all known alternatives, including those previously regarded as unacceptable; (g) develop sufficiently detailed plans for implementing the chosen policy, with special reference to contingency plans in the event known risks materialized. As Janis (1972, p. 10) noted, the outcomes of groupthink decisions *deserved* to be fiascoes "because of the grossly inadequate way the policy makers carried out their decision-making tasks."

Janis contrasted the groupthink decisions with two examples of well-worked-out foreign policy decisions: the development of the Marshall Plan and the handling of the Cuban Missile Crisis. In these instances, the decision-making groups and their leaders gave high priority to critical appraisal and open discussion of policy options. "Decision makers had to undergo the unpleasant experience of hearing their pet ideas critically pulled to pieces" (Janis, 1972, p. 165). The policies ultimately developed within these groups were based upon careful analysis of the likely consequences of large numbers of policy options, with frequent attempts at proposing new solutions that maximized the advantages and minimized the disadvantages of options already analyzed.

Janis provided no quantitative evidence bearing on the validity of his classification of foreign policy deliberations into the groupthink and non-groupthink categories.

> For purposes of hypothesis construction—which is the stage of inquiry with which this book is concerned—we must be willing to make some inferential leaps from whatever historical clues we can pick up. (Janis, 1972, p. v)

Unfortunately, the most appropriate documents for testing the groupthink hypotheses

—verbatim records of formal and informal meetings among decision makers—were not available. The historical clues upon which Janis relied—observer accounts of private conversations and participant memoirs—were susceptible to serious retrospective distortion of a motivational or cognitive nature (cf. Fischhoff & Beyth-Marom, 1976, on the "certainty-of-hindsight" bias). Moreover, Janis did not specify the criteria that he used in deciding to include or exclude data. Thus, he may inadvertently have given too much weight to evidence that supported group think hypotheses and too little weight to contradictory evidence.

A wide range of behavioral research methods can be used to test Janis's analysis. Two possible approaches are (a) laboratory simulation studies that factorially manipulate hypothesized determinants of groupthink and then observe effects on social interaction and quality of decision making, and (b) content analysis studies of archival records that cast light on how decision makers think in actual crises. Each approach has compensating methodological advantages and disadvantages.

Flowers's (1977) research exemplifies the first approach. In a 2 × 2 laboratory experiment, Flowers found that "open-leadership style" led groups to suggest more solutions to a problem and to use more available information than "closed-leadership style." This finding was compatible with Janis's (1972) analysis. Contrary to Janis, though, "degree of group cohesiveness" did not affect quality of decision making. This latter finding is, however, difficult to interpret. On the one hand, Janis's theory may need revision. On the other hand, Flowers's operational definition of cohesiveness (using groups of college students) probably differs from the cohesiveness displayed within foreign policy–making groups (who have typically known each other for many years and are confronted by extremely ego-involving tasks). The interpretive ambiguity reflects a fundamental limitation of simulations: the impossibility of ensuring that a simulation fully captures the processes operating in the original situation (cf. Bem, 1972).

The present study takes the second approach. It applies standardized content analysis procedures to statements of key decision makers involved in the groupthink and non-groupthink crises that Janis examined. Relative to laboratory studies, the primary advantage of this approach is the high external validity achieved by dealing with real-life decisions by top policy makers; the primary disadvantage is the relative lack of control over both independent and dependent variables.

With respect to independent variables, the laboratory researcher can often be confident that his or her experimental conditions differ in only a few theoretically relevant ways. Whether the same can be said for the hypothesized groupthink and non-groupthink foreign policy decisions is unclear. As is almost inevitable in comparing complex naturally occurring phenomena, possible confounding variables exist. For instance, the groupthink decisions all involved military interventions or escalations of questionable success; the non-groupthink decisions involved more restrained policies having desirable consequences (from the standpoint of the decision makers). It is debatable, however, whether these differences are independent of or attributable to groupthink. For example, Janis (1972) suggested that groupthink predisposes decision makers to seek rapid, clear-cut military solutions to complex problems. Nonetheless, it is important to keep in mind that the groupthink/non-groupthink contrast in this study can be reconceptualized as a contrast between unsuccessful military and successful nonmilitary national policies.

With respect to dependent variables, the laboratory researcher has relatively direct access to subjects' decision-making deliberations. Such records are much less accessible when one's subjects are heads of state and their advisors. Currently, the only standardized records of how groupthink and non-groupthink decision makers perceived policy options consist of decision makers' public statements during the relevant crises. This need not, however, be a serious liability. Although public statements are undoubtedly more influenced by efforts to manage polit-

ical impressions than are private statements, there are good reasons to assume that manifestations of groupthink will appear in both private and public statements. Political elites —for a variety of reasons—probably do not frequently endorse policy positions that are very dissimilar to those they endorse in private (cf. Graber, 1976). Political leaders are usually concerned with maintaining an image of trustworthiness that would be jeopardized by failure to maintain some consistency between their words and deeds (cf. Graber, 1976; Tedeschi, Schlenker, & Bonoma, 1971). To the extent that groupthink seriously interferes with the cognitive efficiency and moral judgment of decision makers, groupthink also probably affects how decision makers attempt to justify their policies to the world.

The study reported here selected content analysis procedures for their appropriateness in identifying two major manifestations of groupthink: (a) the tendency to process policy-relevant information in simplistic and biased ways, and (b) the tendency to evaluate one's own group highly positively and to evaluate one's domestic and international opponents highly negatively. These variables were selected partly because they are more likely to be revealed at an overt or public level than others (e.g., self-censorship of doubts, direct pressuring of deviants, or the emergence of mindguards) and partly because reliable and valid measurement techniques could be readily adapted for the purpose of assessing them.

The integrative-complexity coding system was used to determine the degree to which "simpler" (i.e., less differentiated and less integrated) modes of information processing prevailed in groupthink situations. The coding system was initially developed as a measure of the integrative-complexity dimension of personality (Harvey, Hunt, & Schroder, 1961; Schroder, 1971; Schroder, Driver, & Streufert, 1967). Recent research indicates that the coding system is also sensitive to situationally induced shifts in complexity of information processing and can be usefully applied to such documents as letters, essays, speeches, and diplomatic communications (Suedfeld, 1978; Suedfeld & Rank, 1976; Suedfeld & Tetlock, 1977; Suedfeld, Tetlock, & Ramirez, 1977). For instance, Suedfeld and Rank (1976) have shown that the integrative complexity of successful revolutionary leaders who subsequently held onto power was higher after victory than before victory, whereas leaders who failed to maintain power after victory did not show such a change. They argued that this finding reflects the need for change from the simple cognitive strategies appropriate to a revolutionary struggle toward the complex approach required of governments in power. Suedfeld et al. (1977) found that the complexity of Arab and Israeli speeches to the United Nations tended to decline prior to the outbreak of major wars. They argued that this finding probably reflects the disruptive effects of stress on complex information processing (see also Suedfeld & Tetlock, 1977). Such data strongly suggest the usefulness of the complexity coding system for unobtrusively assessing cognitive structural variables from archival data and, most relevant here, for testing Janis's groupthink analysis.

Evaluative assertion analysis was used to test the hypotheses concerning the effects of groupthink on "in-group" and "out-group" attitudes (see Osgood, 1959; Osgood, Saporta, & Nunnally, 1956). The technique has grown out of Osgood's research on the dimensions of meaning and the congruity principle of attitude change. It has been used successfully in a wide variety of research projects, including the coding of psychotherapeutic interviews (Osgood, 1959), the examination of John Foster Dulles's attitude toward the Soviet Union (Holsti, 1967), and the assessment of bias in the news coverage of presidential candidates (Westley et al., 1963). The common purpose underlying the diverse applications of evaluative assertion analysis has been "to extract from verbal communications the evaluations being made of significant concepts" (Osgood et al., 1956, p. 47). The significant concepts in the present context are defined as *groups with which the speaker identifies* and *domestic and foreign opponents*.

In summary, this study employed two independent techniques of content analysis to test hypotheses abstracted from Janis's case studies of groupthink in American foreign

policy making. The integrative-complexity coding system was used to assess the relative differentiation and integration of decision makers' public statements in groupthink and non-groupthink crises. Evaluative assertion analysis was used to assess the direction and intensity of in-group and out-group attitudes in these situations.

Method

Archival records of public statements by leading decision makers in five American foreign policy crises provided the data for the current study. Statements were drawn from primary sources that included the *United States Department of State Bulletin*, the *Congressional Record, Collected Papers of the Presidents of the United States,* and *Vital Speeches*. The decision makers for whom materials were scored included: the Marshall Plan—President Harry S. Truman, Secretary of State George C. Marshall, Undersecretary of State Dean Acheson; the invasion of North Korea—President Harry S. Truman, Secretary of State Dean Acheson; the Bay of Pigs invasion—President John F. Kennedy, Secretary of State Dean Rusk; the Cuban Missile Crisis—President John F. Kennedy, Secretary of State Dean Rusk; The Vietnam War escalation decisions—President Lyndon B. Johnson, Secretary of State Dean Rusk. Public statements were taken from the following time periods: the Marshall Plan—May 1, 1947 – December 19, 1947; the invasion of North Korea—September 10, 1950 – November 20, 1950; the Bay of Pigs invasion—January 20, 1961 – April 20, 1961; the Cuban Missile Crisis—October 16, 1962 – October 29, 1962; the Vietnam War escalation decisions—December 1, 1964 – July 1, 1965. A total of 12 (paragraph-sized) passages were randomly selected for each major decision maker within each crisis period.

A topic restriction was enforced. Public statements were analyzed only if the material was primarily concerned with the foreign policy decision on which the Janis case studies focused. The primary reason for this restriction is uncertainty regarding the degree to which groupthink in one topic area generalizes to other areas. The following guidelines were used:

1. The Marshall Plan. All statements pertained to the economic state of Europe and the role that American aid could play in facilitating recovery.

2. The invasion of North Korea. All statements pertained to the conduct of the war and political and moral justifications for the war.

3. The Bay of Pigs invasion. All statements pertained to the dangers presented by the Castro government in Cuba and to the role of the United States in helping prevent expansion of Communist influence in Latin America.

4. The Cuban Missile Crisis. All statements pertained to the threat posed by the actions of the Soviet Union in Cuba.

5. The Vietnam War escalation decisions. All statements pertained to the danger of the Communist threat in Southeast Asia and the need for American aid to defend the non-Communist governments in the region.

The Bay of Pigs invasion posed unique problems for obtaining data. Since the invasion was a secret operation, decision makers did not describe or justify the invasion policy in their public statements. In this sense, the Bay of Pigs case differs from the other four crisis situations examined. Data analyses have been performed both with and without the data collected from the Bay of Pigs time period.

Integrative-Complexity Coding

All material was scored for integrative complexity on a 7-point scale (see Schroder, Driver, & Streufert, 1967, Appendix 2, for detailed discussion of the coding rules). The scale defines complexity in terms of both differentiation and integration. Differentiation refers to the number of characteristics or dimensions of a problem situation that are recognized and taken into account in decision making. For instance, a decision maker may process information relating to policy options in an undifferentiated fashion by placing options into only one of two categories: the "good, patriotic" policies and the "bad, defeatist" policies. A more differentiated approach would recognize that policy options can have multiple, often contradictory effects that cannot be classified on a single evaluative dimension of judgment—for example, effects on different political constituencies, various sectors of the economy, military strength, and the strategies of one's opponents. Integration refers to the development of complex connections among differentiated characteristics. (Differentiation is thus a prerequisite of integration.) The complexity of integration depends on whether the dimensions of judgment employed by the decision maker are perceived as operating in isolation (low integration), in hierarchical interaction (medium integration), or according to multiple, complex, and perhaps flexible patterns (high integration). Scores of 1 reflect low differentiation and low integration. Scores of 3 reflect medium or high differentiation and low integration. Scores of 5 reflect medium or high differentiation and medium integration. Scores of 7 reflect high differentiation and high integration. Scores of 2, 4, and 6 represent transition points between adjacent levels.

Initial scoring for integrative complexity was performed by the author and Peter Suedfeld, who were, however, both aware of the hypotheses being tested and the sources of the material (interrater agreement $r = .91$). The reliability of this scoring was checked by having material rescored by trained coders associated with a research group under Suedfeld at the University of British Columbia. These coders were blind to both the hypotheses being tested and the

Table 1
Attitude Objects Included Under General Categories of "Domestic and Foreign Opposition" and "Groups With Which Speaker Identifies"

Marshall Plan
Opposition
Communism, USSR, East European Communist states, Communist parties of Western Europe, totalitarian regimes, Communist victories, fall of Europe
Groups with which speaker identifies
American government, American people
Invasion of North Korea
Opposition
Communism, USSR, North Korea, Communist China, forces of Communism, Communist imperialism, new colonialism, Soviet leaders
Groups with which speaker identifies
American government, American people, United Nations Command in Korea, South Korea, UN soldiers, we, American history to the present, policy of increasing strength
Bay of Pigs invasion
Opposition
Communism, USSR, Castro's Cuba, alien ideology, Communist agents
Groups with which speaker identifies
American government, American people, Cubans opposed to Castro government, those concerned with maintaining peace, our long-range aspirations, Kennedy, our (OAS) delegates, anti-Castro guerrilla fighters, Cuban people, security of Latin America
Cuban Missile Crisis
Opposition
Communism, USSR, Castro's Cuba, new Soviet moves, Khrushchev's decision, extracontinental power
Groups with which speaker identifies
American government, American people, nations of this hemisphere, unanimity of Western Hemisphere, free nations
Vietnam War escalation decisions
Opposition
North Vietnamese, Viet Cong, Red China, USSR, aggressors, yielding to aggression, policy of withdrawal
Groups with which speaker identifies
American government, American people, South Vietnamese government, policy of standing firm

sources of the material. High interrater agreement ($r = .88$) was obtained between the complexity ratings assigned by persons aware and unaware of the hypotheses. Analysis of disagreements revealed no relationship to the groupthink hypothesis.

Evaluative Assertion Analysis

Evaluative assertion analysis was performed on the same materials. (Osgood et al., 1956, present a more detailed discussion of how to perform evaluative assertion analysis.) The analysis involved four basic stages and was performed by two coders, one of whom was the author; the other was an individual otherwise uninvolved in the study. The first stage of the evaluative assertion analysis was the identification and isolation of attitude objects. Two general classes of attitude objects were selected for analysis: *political groups with which the speaker identifies* and *domestic and foreign opponents*. Table 1 presents the variety of specific terms taken from public statements that were considered to fall into one of these two general categories. It was possible to obtain extremely high interrater agreement for identifying and classifying these terms. Disagreements were resolved by using the judgments of the coder unaware of the hypotheses.

The second stage involved translating all statements in which these attitude objects appeared into one of two common sentence forms:

Attitude Object 1 / Verbal connector / Common meaning term
Attitude Object 1 / Verbal connector / Attitude Object 2.

For example, the sentence "An aggressive North Korea threatens freedom-loving South Korea" would be translated to read:

North Korea / is / aggressive
North Korea / threatens / South Korea
South Korea / is / freedom loving.

Here, again, coding disagreements were rare and were resolved by using the judgment of the blind coder.

In the third stage, the verbal connectors and predicates were rated for intensity and direction on 7-

point scales ranging from −3 to +3. A verbal connector received a negative score to the degree that it dissociated the subject from the predicate ("never is" would receive a score of −3) and a positive score to the degree that it associated the subject and the predicate ("always is" would receive a score of +3). A predicate received a negative score to the degree that it represented a negatively evaluated attribute or quality (e.g., evil, aggressive) within "the language community of the speaker" (Osgood et al., 1956). The predicate received a positive score to the extent that the attribute or quality cited was positively evaluated within the language community of the speaker (e.g., freedom, peace). Reliability checks were obtained to ensure that verbal connectors and common meaning terms were being assigned ratings that reflected common linguistic standards. The correlations of coder ratings of verbal connectors and common meaning terms were .93 and .94, respectively.

The direction and intensity of evaluative sentiment directed toward each of the two categories of attitude objects were computed for each paragraph unit. Within each unit, references to each of the two classes of attitude objects were separated. The direction and intensity of evaluative sentiment directed to each class were computed by (a) multiplying the values assigned to the verbal connectors and predicates used to describe attitude objects falling within the class and (b) summing the products thus obtained. Two scores were obtained in this way for each paragraph unit from the evaluative assertion analysis: One specified the intensity and direction of evaluative feeling toward political groups with which the speaker identified, and the other specified evaluative feeling toward the speaker's opponents.

Results

Unweighted-means analyses of variance were used to test the groupthink hypotheses. The analyses of variance always involved three independent variables: type of crisis (groupthink vs. non-groupthink), decision makers within crises, and the random ordering of the 12 passages of material sampled from each decision maker's statements.

The analyses of variance were complicated by the fact that individual decision makers were unevenly represented across different crisis situations. In analysis of variance terms, decision makers were partly "crossed" with and partly "nested" within crises. For instance, Truman and Acheson both appeared in the 1947 (non-groupthink) and 1950 (groupthink) crises (that is, they were crossed with these two crises); similarly, Kennedy and Rusk both appeared in the 1961 (groupthink) and 1962 (non-groupthink) crises. Neither pair of decision makers appeared in crises involving the other pair. Marshall appeared only in the 1947 crisis, and Johnson appeared only in the 1964–1965 (groupthink) crisis. Finally, Rusk appeared most frequently: in the 1961, 1962, and 1964–1965 crises.

To resolve this complicated situation, it was assumed that different decision makers were involved in each crisis (i.e., decision makers have been treated as nested within crises). This assumption was conservative in the sense that it reduced the likelihood of detecting significant differences between groupthink and non-groupthink crises. The assumption sacrifices the opportunity to control statistically for the effects of personality variables. The groupthink effect must overcome personality effects in order to be detected.

A second, conservative assumption was also made. In all analyses of variance, the groupthink and non-groupthink crises have been treated as random effects. The crises were viewed as a sample from the population of groupthink and non-groupthink decisions. For this reason, quasi-F ratios have been constructed to test the significance of crisis effects (cf. Clark, 1973; Winer, 1971). These quasi-F ratios are smaller than the ordinary F ratios that would have been appropriate if crises were viewed as a fixed variable.

Table 2 presents the mean integrative complexity scores of each major decision maker within each crisis. Consistent with the groupthink hypothesis, a planned orthogonal contrast of complexity scores revealed that decision makers in groupthink crises were significantly less complex than their counterparts in non-groupthink crises, quasi-$F(1, 17) = 18.29$, $p < .01$. This effect remained significant when the data obtained from the Bay of Pigs period were deleted, planned contrast, quasi-$F(1, 16) = 15.77$, $p < .01$. No other effects were significant.

Decision makers' mean evaluations of political groups with which they identified are also presented in Table 2. As predicted, decision makers in groupthink crises evaluated political groups with which they identified more positively than did decision makers in non-groupthink crises, planned contrast, quasi-

Table 2
Mean Ratings on the Three Dependent Variables

Decision maker	Integrative complexity	Evaluation of group with which speaker identifies	Evaluation of opponents
Non-groupthink crises			
1947			
Truman	3.66	5.5	− 1.75
Acheson	4.5	.666	− 1.0
Marshall	5.9	0	− .166
1962			
Kennedy	4.33	2.92	0
Rusk	3.16	2.0	− 4.08
Groupthink crises			
1950			
Truman	1.0	14.0	−10.5
Acheson	1.83	13.33	− 1.92
1961			
Kennedy	2.16	12.33	− 6.25
Rusk	2.58	9.833	− 4.0
1964–1965			
Johnson	2.16	4.83	− 9.83
Rusk	2.5	3.33	− 2.92

$F(2, 17) = 17.37$, $p < .01$.[1] This effect remained significant when the data obtained from the Bay of Pigs period were deleted, planned contrast, quasi-$F(1, 16) = 8.03$, $p < .05$. No other effects were significant.

Table 2 also presents decision makers' mean evaluations of domestic and foreign opponents. Contrary to theoretical expectations, there was no significant difference between groupthink and non-groupthink crises in negative evaluations of domestic and foreign opponents, planned contrast, quasi-$F(1, 13) = 2.9$, $p < .15$. The effect remained nonsignificant when data from the Bay of Pigs period were deleted, planned contrast, quasi-$F(1, 11) = 2.34$, $p < .25$. In both analyses, the difference was in the direction predicted by the groupthink analysis. The other effects were also nonsignificant.

Low significant correlations existed between integrative complexity and the evaluative assertion analysis measures. More complex statements tended to include fewer positive evaluations of political groups with which the speaker identified, $r(130) = -.27$, $p < .001$, and fewer negative evaluations of domestic and foreign opponents, $r(130) = .33$, $p < .001$.

A major disadvantage of treating decision makers as nested within crises is that it prevents comparison of how individuals who appeared together in two crises (e.g., Truman and Acheson; Kennedy and Rusk) reacted in the different situations. For example, one decision maker may have been highly consistent in the integrative complexity and evaluative intensity of his public statements, whereas another may have been highly inconsistent. To examine this hypothesis, matched-pairs t tests were performed on the data obtained from Truman and Acheson in the crises in which they appeared (1947 and 1950) and on data obtained from Kennedy and Rusk in the crises in which they appeared (1961, 1962, and in the case of Rusk, 1964–1965). The results indicated that public statements of individual decision makers did not always change in the directions predicted by the groupthink analysis. While Truman's, Acheson's, and Kennedy's statements were less

[1] Degrees of freedom for the quasi-F statistics were calculated using Satterthwaite's formula (see Winer, 1971, pp. 375–378). With this formula, it is possible for numerator degrees of freedom of a planned contrast to be greater than one.

complex in groupthink than in non-groupthink situations, the complexity of Rusk's statements remained relatively constant through the 1961, 1962, and 1964–1965 crises. Truman's evaluations of opponents were significantly more negative during the 1950 crisis (relative to the 1947 crisis), but his evaluations of political groups with which he identified were not more positive. Acheson's evaluations of political groups with which he identified were, however, more positive in the 1950 crisis (relative to the 1947 crisis), but his evaluations of opponents were not significantly more negative. Kennedy's public statements changed most in conformity with the groupthink model. Between the Bay of Pigs and the Cuban Missile Crisis, Kennedy showed significant or marginally significant changes in the predicted direction on integrative complexity, evaluations of opponents, and evaluations of political groups with which he identified. Rusk's public statements were least in conformity with the groupthink model. He showed no significant shifts on any of the three dependent variables between the 1961 and 1962 crises or the 1962 and 1964–1965 crises. In sum, evidence exists for individual differences in decision makers' reactions to groupthink and non-groupthink situations.

An important unresolved issue is how to determine whether groupthink is occurring in given situations. The present research suggests that relatively objective content analysis procedures applied to the public statements of decision makers may be useful for this purpose. As a first step toward developing clear criteria for distinguishing groupthink and non-groupthink decisions, discriminant analysis was used to evaluate the usefulness of the three dependent variables employed in this study in differentiating groupthink and non-groupthink decisions (cf. Cooley & Lohnes, 1971).

The discriminant function obtained was significant at the .001 level, $\chi^2(3) = 72.7$, and accounted for 45% of the total variation between groups. The standardized discriminant function coefficients for maximally distinguishing the two groups were (a) integrative complexity, .89; (b) evaluations of political groups with which speaker identifies, −.21; and (c) evaluations of domestic and foreign opponents, .08. This pattern indicates that public statements in groupthink crises can be best distinguished from public statements in non-groupthink crises on the basis of integrative complexity and, to a lesser extent, evaluations of political groups with which the decision makers identify. The "evaluations of opponents" variable appears to have no independent discriminatory power. The discriminant function correctly predicted the groupthink or non-groupthink origins of 78% of the public statements.[2]

Discussion

The results for two of the three dependent variables strongly supported the predictions derived from Janis's groupthink analysis. Public statements of decision makers in groupthink crises were characterized by significantly lower levels of integrative complexity than the public statements of decision makers in non-groupthink crises. Decision makers in groupthink crises evaluated political groups with which they identified more positively than did decision makers in non-groupthink crises. However, contrary to expectation, groupthink and non-groupthink decision makers did not significantly differ in the intensity of their negative evaluations of domestic and international opponents.

With the exception of the last dependent variable, the current findings converge impressively with the conclusions of Janis's intensive case studies. The convergence is impressive primarily because the findings of this study and those of Janis (1972) are based upon markedly different types of data (public statements versus the retrospective accounts of observers and participants) that have been processed in very different ways (quantitative content analysis vs. intuitive reconstruction of historical episodes). The present study underscores how multiple methods of investigation—ranging from case studies to content analysis studies to laboratory experiments—

[2] A separate discriminant analysis was performed without the Bay of Pigs data. The results did not differ substantially from those reported above.

an be brought together to test the validity of ne groupthink construct.

Nonetheless, it is appropriate to introduce cautious note. The evidence reported here loes not rule out all alternative explanations. The skeptic can point out that the groupthink and non-groupthink crises differed in ways that render interpretation of the results somewhat ambiguous. For instance, as noted earlier, the groupthink decisions all led to unsuccessful military interventions or escalations, whereas the non-groupthink decisions did not lead to significant military action. Differences in public statements prior to these decisions may reflect differences in propaganda strategies used to convince the American public to accept military or nonmilitary solutions to conflicts. Political leaders may justify militaristic decisions by emphasizing in simple terms their total opposition to the enemy and their total dedication to their own nation's values. The disadvantage of this interpretation is that, unlike the groupthink model, it cannot explain most of the available historical evidence on the behavior of policy makers in the relevant crises (see De Rivera, 1968; Graff, 1970; Janis, 1972; Neustadt, 1964). The propaganda explanation accounts only for the results of the content analyses of public statements.

A decisive test of the groupthink and propaganda explanations will probably elude us for a long time. At least two lines of further research can, however, help to clarify the applicability of the competing positions in particular historical settings. One (still not feasible) approach is to compare the private statements of decision makers in the hypothesized groupthink and non-groupthink crises. If groupthink is operating, manifestations of the syndrome should appear in private and public statements. If the propaganda position is correct, there is no reason to expect the private statements of groupthink and non-groupthink decision makers to differ, even though significant differences would emerge in their public statements. A second approach is to draw upon case studies in the historical and political science literatures to identify a much larger sample of probable groupthink and non-groupthink decisions, some of which have led to war and some of which have not. If the propaganda position is correct, symptoms of groupthink should appear in public statements prior to the decision to go to war, independently of how the decision was made. If the groupthink position is correct, manifestations of groupthink should appear only in the public statements of the groupthink decision makers.

Regardless of whether the war propaganda or groupthink interpretation of this study is correct, the results reported here have intriguing practical implications. The propaganda interpretation suggests that it should be possible to predict in advance the occurrence of military interventions or escalations using content analysis indicators of integrative complexity and attitude polarization. The groupthink interpretation suggests that it should be possible to use the same content analysis indicators to monitor the quality of decision making of governmental leaders. Such monitoring activity may have the beneficial effect of sensitizing policy makers to the manner in which they make decisions and may, in the most optimistic of scenarios, lead to improvements in the quality of their decision making.

Finally, a few comments are in order concerning the lack of significant differences in negative evaluations of opponents in the groupthink and non-groupthink crises. This result is puzzling for both the groupthink and war propaganda explanations (indeed, perhaps especially puzzling for the propaganda explanation). There may, however, be a methodological reason for the result. Content analyses of public statements may be insensitive to differences in evaluations of opponents in groupthink and non-groupthink crises. In this regard, the fact that the public statements sampled contained 33% fewer negative than positive evaluative assertions is suggestive. This finding is not surprising in view of the considerable social psychological evidence indicating that people are more likely to offer positive than negative evaluations and that persons giving positive evaluations are themselves regarded as more attractive than those giving negative evaluations (see Folkes & Sears, 1977). It is probably effective impression management for politicians to "accentuate the positive" in their

public statements. Diplomatic norms may add further pressure in this direction. An advocate of the groupthink position could simply argue that groupthink decision makers were reluctant to express fully their negative feelings toward opponents.

The argument above points again to the need for research that analyzes verbatim records of actual group deliberations. A more conclusive test of the groupthink analysis awaits the declassification of such documents.

The Birth Order Puzzle

R. B. Zajonc, Hazel Markus, and Gregory B. Markus
University of Michigan (Ann Arbor)

Studies relating intellectual performance to birth order report conflicting results, some finding intellectual scores to increase, others to decrease with birth order. In contrast, the relationship between intellectual performance and family size is stable and consistently replicable. Why do these two highly related variables generate such divergent results? This birth order puzzle is resolved by means of the confluence model that quantifies the influences upon intellectual growth arising within the family context. At the time of a new birth, two opposing influences act upon intellectual growth of the elder sibling: (a) his or her intellectual environment is "diluted" and (b) he or she loses the "last-born's handicap" and begins serving as an intellectual resource to the younger sibling. Since these opposite effects are not equal in magnitude, the differences in intellectual performance among birth ranks are shown to be age dependent. While elder children may surpass their younger siblings in intellectual performance at some ages, they may be overtaken by them at others. Thus when age is taken into consideration, the birth order literature loses its chaotic character and an orderly pattern of results emerges.

> Reuben, you are my first born, my might, and the fruits of my strength, pre-eminent in pride and pre-eminent in power. (Genesis 49:3)

In most societies some individuals come to control great wealth, to wield enormous power, and to acquire coveted honors, titles, and privileges just by virtue of their position in the family. Faith in superior endowment of the first offspring has fostered laws of succession, inheritance, and intestacy favoring the firstborn child—especially the male child—that still prevail in many countries. In fact, it was not until the turn of the century that this faith and the corresponding laws of primogeniture were challenged. At this time, geneticists, pathologists, and psychologists began to explore the question from a variety of perspectives, and indeed, the first studies appeared to provide empirical substance for the belief in the superiority of the eldest (cf. Ellis, 1904; Galton, 1874; Gini, 1915). For example, Cattell and Brimhall (1921) published their observations on the birth rank of scientists and concluded that the firstborn is to be found in greater frequency among scientists than the later born, and that this overrepresentation occurs for all family sizes.

With continued attention to this question, however, contradictory results soon began to appear. Thurstone and Jenkins (1929) examined a large number of children and concluded quite explicitly:

> On the whole the *later* born siblings tend to be on the average brighter than the first-born. Not only does this seem to be the case in the comparison of the first-born with the subsequent children, but the rise in intelligence with the order of birth seems to continue as far as the eighth-born child. (p. 649)

In a subsequent study, Steckel (1930) substantiated Thurstone's results.

Other studies followed. Some reported increments with birth order, some decrements, and several failed to find any relationship whatever. Among studies that found decreasing intelligence or scholastic scores with birth

order were those of Altus (1965), Bayley (1965), Breland (1974), Belmont and Marolla (1973), Lunneborg (1968, 1971), and Schachter (1963). Increases in intelligence scores with birth order were reported by Arthur (1926), Commins (1927), Hill (1936), Koch (1954), and Willis (1924). In a study by Hsiao (1931), some samples showed a positive relationship with birth order and others a negative relationship. And Bayer (1966) and McCall and Johnson (1972) failed to find any relationship whatever between birth order and intelligence. The latter authors suspected, in fact, that the correlations of IQ with birth order approach zero "in those studies where more careful attention is given to sample design and to subsequent controls" (p. 208). The research literature on birth order appeared so confused that one serious reviewer was prompted to declare birth order unworthy of further research efforts (Schooler, 1972).

In contrast to the inconsistencies among the birth order data are the results on the intellectual consequences of family size (Terhune, 1976). Figure 1 shows the results of surveys of the intellectual levels of six large populations. In spite of differences in age, sex, nationality, and type of test given, they all show a strikingly similar pattern of decline in scores with family size.

This, then, is the birth order puzzle. Why is the effect of family size such a consistent one, showing itself over and over again in the literature, while at the same time the effect of birth order—a closely related factor—presents such a chaotic picture? The birth order problem is especially troublesome, for none of the variables examined in the literature can organize these results into an orderly set of generalizations. For example, the suspicion that birth order effects are found primarily on verbal proficiency tests is seriously undermined by the strong effects found also with the Raven Progressive Matrices Test (Belmont & Marolla, 1973). The possibility that socioeconomic factors may mediate these effects is dispelled by several studies (e.g., Institut National d'Etudes Démographiques [INED], 1973; Claudy, Note 1) showing parallel effects for a variety of socioeconomic status categories. Cohort effects, too, are soon ruled out as a possibility because Galton's cohort of the 19th century showed effects no different from those of the much later cohort examined by Cattell and Brimhall (1921) nor from those of the most recent cohort of high school seniors examined by Claudy (Note 1).

A recent analysis of intellectual development may supply a solution to the birth order puzzle. A model termed *the confluence model* (Markus & Zajonc, 1977; Zajonc, 1976; Zajonc & Markus, 1975) was developed to explain a large body of intelligence data published in 1973 by Belmont and Marolla. These data on birth order and family size exhibited five important features: (a) intelligence scores declined with family size; (b) within each

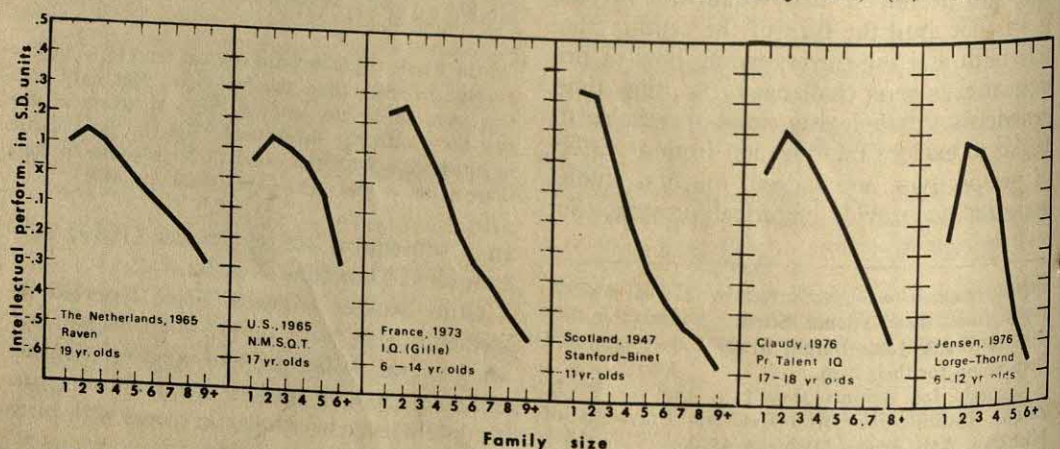

Figure 1. Family size (number of children) and intellectual performance in six large samples. (S.D. = standard deviation; N.M.S.Q.T. = National Merit Scholarship Qualifying Test.)

family size they declined with birth order; (c) if the last child was ignored, the decline with birth order seemed to be decelerated; (d) the decelerating birth order trend was not followed by the last child, who showed a discontinuous drop in intellectual performance; and (e) the only child, too, showed a discontinuity in that if the family factor were systematically negative in influencing IQ, the only child should have had the highest average of all, which was not the case, as can be clearly seen in Figure 1. The confluence model was constructed to reflect these features of the Belmont–Marolla data, and it has been refined since its original publication to accommodate new data (see Appendix).

The Confluence Model

The basic assumption of the confluence model, both in its earlier and its reparametrized version presented here, is that family influences that contribute significantly to intellectual growth can be divided into two sources. Specifically, the rate of intellectual growth is hypothesized to be a function of the intellectual environment within the family, α, and a factor, λ, associated with the special circumstances of last children.

The intellectual environment is defined to be a function of the absolute intellectual levels of all family members, including the individual whose intellectual development is being analyzed.[1] These intellectual levels are not to be confused with IQ, which is a measure relative to age. Nor are they to be confused with mental age, whose population means are commonly set equal to chronological ages. Rather, they are absolute quantities that reflect each individual's mental maturity. One could think here, for example, of the individual's vocabulary, which is accumulated not in constant increments but according to a sigmoid function.

As the family members mature, the intellectual environment changes, and the most pronounced changes are likely to occur when new children are born into the family or when grown members leave. Since infants are intellectually immature, their births depress the average intellectual level in the family. Moreover, the smaller the family, the greater is the impact of a new birth (or a departure of an adult) on the resultant intellectual environment. Therefore, the major family configuration variables that affect α are family size and length of intervals between the births of successive siblings.

The term λ reflects the two discontinuities found in the Belmont–Marolla data for only and last children. These discontinuities exist, it is hypothesized, because of a particular disadvantage suffered by all last children, including only children. The intellectual responsibilities of older and younger children differ within the family. Specifically, only and last children are not teachers in the broad sense of the word, and it is assumed that the relatively low performance scores often reported for them in the literature are associated with this lack of teaching opportunity.[2]

Since last-born children do not normally serve as intellectual resources to their siblings, a condition assumed to enhance intellectual growth (Zajonc & Markus, 1975), and since, except for twins, each child is at some age the last child in the family, the rate of intellectual growth during such periods is affected accordingly. Specifically, λ_t will be equal to zero throughout the period when the child is last born and will take on a positive value once a younger sibling is born. It is assumed, furthermore, that the beneficial effects of the teaching function vary with age too, and that they vary not only with the age of the individual who provides tutoring but also with the age of the individual who receives it. One cannot

---

[1] We shall use the term *family* to include also individuals who are not related to each other (such as permanent guests, domestic help, etc.) but who live in the home and can be considered to be members of the immediate intellectual environment.

[2] While there are no studies on the teaching function in the family, some recent research has shown the substantial benefits that are derived by tutors in school cross-peer teaching programs (Devin-Sheehan, Feldman, & Allen, 1976; Duff, 1974; Morgan & Toy, 1970; Richer, 1973; Wu, 1973). In most cases the benefits accruing to the tutor exceed those accruing to the tutee. In one study, for example, there was a 9-month gain on the Wide Range Achievement Test for tutors and only a 3-to-5-month gain for their charges (Morgan & Toy, 1970).

do much tutoring at an age less than 2 years, and little tutoring can be administered to an infant. The term λ_t reflects these considerations, in the reparametrized version of the model, representing them as the product of the two increments—that pertaining to the individual whose mental maturity is being calculated and that pertaining to the next sibling. All members of the family, except the last born, serve as intellectual resources to one another. The benefits that derive from this function are therefore divided among the parents and all the children but the last one. Thus, λ_t has $n - 1$ in its denominator.

Birth order has no independent effect on intellectual development within the confluence model. Instead, effects previously thought to be associated with birth order are posited to be mediated substantially by family size and the spacing of births. Short intervals force later-born children to spend a larger portion of their period of growth in a family environment "diluted" by the presence of young children. As intervals between successive children increase, new children enter relatively more advanced environments that enhance their growth. Hence the birth order effects may be mitigated or even reversed by variations in birth intervals (Markus & Zajonc, 1977; Zajonc, 1976; Zajonc & Markus, 1975). The reparametrized confluence model provides a fairly exact fit (obtained by means of iterative procedures) for all of the large data sets thus far analyzed, responding well to the wide variety of patterns of empirical results, some of which show a negative effect of birth order on intelligence, others a U-function or no effect at all.

Dynamics of the Intellectual Environment and Individual Patterns of Growth

According to the confluence model, the intellectual environment changes continually as family members mature and as the family expands (or contracts). Hence, entries at different points into this dynamic environment must result in radically different patterns of growth. Some children may grow up in a family environment marked by abrupt shifts that are occasioned by many additions or departures, whereas their siblings might enter a different time segment of the same environment, where changes are much more gradual. As a consequence, comparisons of intellectual levels at one point in time in the family history or at a given age may yield different values from those obtained from comparisons made at another time. The age at which birth order effects are evaluated is thus of pivotal significance, and the major concern of the remainder of this article is with these variations in birth order effects that occur as a function of the age of testing.

The dependence of birth order effects on age is one of the unanticipated discoveries of the confluence model. This dependence can be readily understood if we consider the growth patterns of only children and children who have just one sibling. Note that, other things constant, only children should develop undisturbed until maturity. There are no events within the family during this period that would cause sharp discontinuities in their rate of growth. Yearly increments in growth are only those that are associated with the maturation of all the family members. For the same reason, the second of two children will also develop undisturbed until maturity (provided that his or her older sibling does not leave home and there are no other major changes in the family situation). In principle, the above statement holds for *all* last children, and it holds *only* for them. The growth rates for these children will show no discontinuities. In contrast, the older of two siblings should manifest a discontinuity in his or her growth pattern, and such discontinuity should coincide with the acquisition of the younger sibling. From his or her own birth until the birth of a younger brother or sister, the first of two children grows at the same rate as the only child. The family conditions of their growth are identical until that age. But when the second child is born, two dramatic changes take place: (a) The average of the intellectual level within the family is decreased by the addition of the immature member and (b) the firstborn acquires a teaching function (i.e., the value of his or her λ_t changes from zero to a positive number).

Dunn (Note 2) reports findings consistent

with these hypothesized changes for young children (18 to 43 months) shortly after they acquire a younger sibling. She observed several specific examples of teaching and caregiving by the older sibling but at the same time found that "when the young siblings play together the firstborn tends to play relatively simple games; he approaches the level of play more appropriate for the younger child" (p. 19).

The birth of a second child can have one of several effects on the firstborn, depending on the assumptions made: (a) If the decrement occasioned by the dilution of the environment due to the new birth exactly equals the gain derived from the teaching function, the growth rate of the firstborn will not be affected at the time of the second child's birth; (b) if the teaching function has an effect more pronounced than the downward change in the value of α, the growth rate of the firstborn will be accelerated; (c) if the initial dilution is more than can be compensated for by the change in λ, however, we may observe an initial depression in the firstborn's growth rate relative to that of the only child.

The first two outcomes would require that the benefits accumulated from teaching a newborn sibling be immediate and large. This possibility seems fairly implausible. The third possibility, which presumes that the benefits from teaching accrue more slowly and gradually, seems more likely. For the range of values of the parameters w_1, w_2, and k (see Appendix), which fit aggregate data such as those of Belmont and Marolla (1973), it is the third effect that is most consistent with the model.

If this third possibility were to obtain, then according to the confluence model the decrement of the firstborn vis-à-vis the only child must be age bound. As the children develop and their intellectual skills increase, the environment within the family gains in quality. The effects of the teaching function, too, cumulate for the firstborn but not for the only child—a condition that could allow the firstborn eventually to surpass the only child, for whom λ always remains equal to zero. This prediction is illustrated in Figure 2, in which

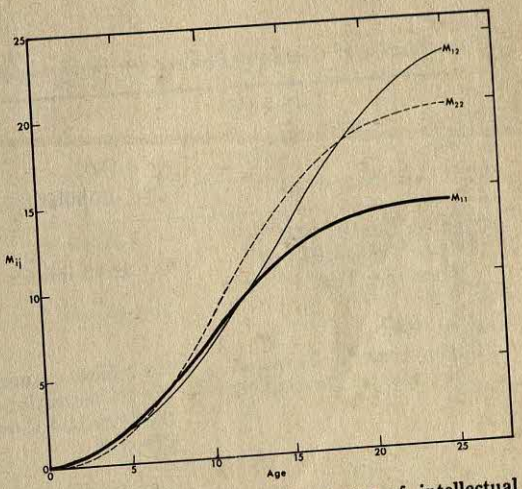

Figure 2. Theoretical growth curves of intellectual levels of only children (M_{11}) and of firstborns (M_{12}) and last borns (M_{22}) in families of two children.

the intellectual levels of the only child and of both siblings in a two-child family are plotted as a function of chronological age.[3] It can be seen in these growth curves that the only child and the first of two grow at the same rate until the latter acquires a sibling at age 5 years. Subsequently, the rate of growth of the firstborn drops below that of the only child. Eventually, the firstborn will surpass the only child, however, and will retain this superiority until maturity, because his or her teaching function continues to cumulate and eventually compensates for the decrement in the α component originally brought about by the acquisition of a younger sibling.

The comparison of the growth rates of the firstborn and second born shown in Figure 2 is also of interest. At birth the second born comes into an intellectual environment that is relatively more impoverished than the one entered by the firstborn. However, the rate of change in these environments is quite different, and the second born can soon exceed the firstborn's rate of growth. Consider, for example, a family with two children whose births are separated by 3 years. At age 8, the intellectual environment of the oldest will reflect the intellectual level of him-/herself (an 8-

[3] The differences between the curves have been exaggerated for illustrative purposes.

year-old), the parents, and the sibling, aged 5. When the last born is 8 years old, however, the environment will consist of him-/herself, the parents, and a sibling aged 11 years. Thus, at a given age the second born's environment may be superior to the environment that sur-

rounded the older sibling at the same age.[4] The accelerated intellectual growth of the second born is temporary, however. Although at a given age the second born may enjoy a superior environment, he or she does not accrue the benefits of the teaching function. The firstborn will benefit by virtue of being a teacher, and the cumulation of this benefit may eventually lead the firstborn to surpass his or her sibling.

The differences in the rates of growth of the first and second children apply equally to all next-to-last and last children. In summary, given the values of the parameters w_1, w_2, and k such as we found for aggregate intelligence data, the confluence model leads to the following expectations:

1. The rate of intellectual growth of the only child and of the first of two is the same until the age when the firstborn acquires a younger sibling.

2. After the birth of the younger sibling, there is a decline in the intellectual environment, and relative to the only child, the rate of growth of the firstborn of two is temporarily depressed.

3. A few years after the birth of his or her younger sibling, the firstborn acquires a teaching function, and thus his or her rate of growth accelerates and eventually surpasses the rate of growth of the only child. At maturity, the first of two will have a higher intellectual level than the only child.

4. Immediately after birth, because of a diluted environment, the second born develops more slowly than did the firstborn at the same age. He or she continues at that lower rate of growth until an age equal to at least the length of the interval separating him/her from the older sibling.

5. The second born can surpass the firstborn at some age equal to at least the interval separating him or her from the older sibling.

6. The advantage of the second born over the firstborn that exists at age levels greater than the birth interval is temporary, and at maturity the firstborn exceeds the second born in intellectual level.

7. The changes in growth rates of first and second children given in 4, 5, and 6 occur for all next-to-last and last children.

Research Evidence

Data that could best reveal the dependence of birth order effects on age predicted by the confluence model would entail the *repeated* observations of entire families. Data of this type should exhibit the expected discontinuities in the growth curves. Unfortunately, information on entire families over time is not available. However, cross-sectional comparisons of individuals of different ages may be made from the existing literature, and although they are indirect, they are quite informative. Table 1 summarizes the literature on birth order effects arranged according to the age of subjects. The studies selected were those in which there was information about sibships of Sizes 1 or 2 and in which birth order effects were not confounded with family size. Studies comparing firstborns and second borns averaged over families of various sizes were thus not included.

Table 1 shows the pattern of results that we would indeed expect on the basis of the confluence model. For very young children the firstborn surpasses the second born. For children of older ages (from about age 3 to 13 years) the birth order effect seems to be reversed. From age 3 years to about age 13 or 14, with almost no exceptions, it is the second born who is higher in intellectual performance. The few exceptions occur at about age 11 (the age of the crossover) or in samples that span several ages. Homogeneous age groups, however, show a consistent pattern. From age 14 up, the superiority of the firstborn reappears and is maintained thereafter without exception. Studies that examine adults never show the second born surpassing the firstborn. For example, Cattell and Brimhall (1921) found firstborns to be overrepresented in *American Men of Science* relative to second borns in two-child families. Gini (1915) reported an overrepresentation of firstborns among Italian university professors, as did Poole and Kuhn (1973) among British university graduates.

Studies on birth order effects with children

[4] It should be clear that the second born's environment will be necessarily superior only at ages greater than the length of the birth interval.

of intermediate ages that were not included in Table 1 because of the confounding of birth order with family size or because of insufficient information, but in which inferences can be made about the likely form of this confounding, are in general agreement with the studies that were included (Kellaghan & MacNamara, 1972; Marjoribanks & Walberg, 1975; McCall, 1973; McCall & Johnson, 1972; Murray, 1971; Oberlander & Jenkins, 1967; Orum, 1971; Steckel, 1930; Thurstone & Jenkins, 1929). Interestingly, many of these studies, especially those having populations of young teenagers, show no birth order effects and often cite their results as counterexamples to other studies that claim birth order to be a significant factor in intellectual development.

Since some studies show negative effects, others positive, and still others no differences at all among the various birth orders, it is clear why birth order acquired such an unsavory reputation as an explanatory variable. But Table 1 reveals that the data on birth order are far from chaotic and that these data can be ordered fairly systematically according to age. The predicted crossover effect is clearly seen in the pattern of the reported

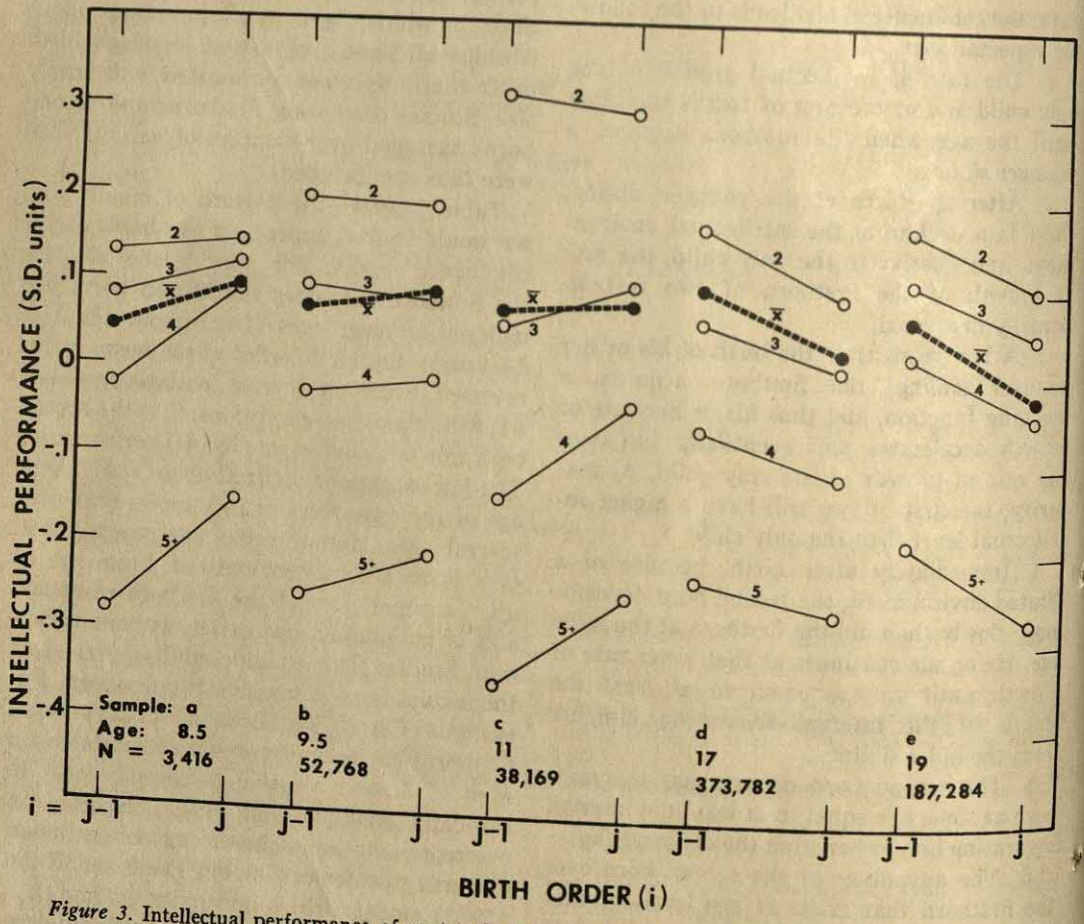

Figure 3. Intellectual performance of next-to-last and last children of different family sizes in five populations differing in age. (Family size is indicated by each curve. $\bar{X}$ indicates the average of all family sizes. The five populations are [a] Berkeley Unified School District study [Jensen, 1974]; [b] *Enquête nationale sur le niveau intellectuel des enfants d'âge scolaire* [INED, 1973]; [c] The trend of Scottish intelligence [Scottish Council for Research on Education, 1949]; [d] National Merit Scholarship Qualification Test Study [Breland, 1974]; [e] Survey of Dutch Recruits [Belmont & Marolla, 1973]. S.D. = standard deviation.)

results. There are two results for children less than 3 years of age. For both, the firstborn shows superiority. There are 12 studies with children aged 3 to 10 years. Of course, 10 show the second born as superior. The remaining 2 results in which the difference in intellectual performance favors the firstborn come from samples that spill over to an older age category, that is, 6 to 14 years (INED, 1973; Jensen, 1974). For the crossover interval 11 to 12 years, 4 results favor the firstborn and 5 favor the second born. Finally, for children over age 12 all results but 1 (18 out of 19) favor the firstborn.

The logic of the predictions indicating how the differential rates at which α and λ contribute to intellectual growth applies to all last and next-to-last children. In this regard, Figure 3 shows the results of five separate surveys of intellectual performance in which ages of the subjects vary from 8.5 to 19 years. The figure shows the scores of the next-to-last and last children in various sibship sizes. It is clear that the pattern found for children in sibships of Size 2 in Table 1 is duplicated quite systematically on all last and next-to-last children. Of the 12 observations of children 11 years of age or younger, the aggregate data favor the second born in 9 cases. Of the 8 observations of older children, all aggregate data show the opposite: The firstborn has a higher score.

Although the pattern of results in Table 1 and Figure 3 is consistent, there remains some ambiguity. Age differences in these results are confounded with a variety of other differences. A homogeneous population of children of different ages tested with the same materials would be virtually free of this confounding. Data of this type were secured from the Institut National d'Etudes Démographiques, which a few years ago conducted extensive surveys of intellectual performance. The second survey carried out by this institution (INED, 1973), examined a sample of more than 125,000 French schoolchildren. It utilized an intelligence measure containing subtests on vocabulary, comprehension, analogies, differences, series completion, and proverbs.[5]

Figure 4 shows intellectual performance of only children and of first- and second borns in two-child families of eight successive age groups.[6] It is clear from the age changes in birth order effects that the predicted patterns are borne out. Among younger children aged 6 to 8 years, the second born surpasses the firstborn. Among the older children this pattern is reversed. Moreover, as predicted, only children score higher than the firstborns among the youngest group, but from age 7 they show a consistent disadvantage. Analyses of variance showed both interactions to be significant, $F(7, 22881) = 2.59$; $p < .01$; $F(7, 22187) = 1.97$, $p < .05$. Figure 4 also shows comparisons for all next-to-last and last children. The pattern of these data is similar to those of two-child families, although the difference in favor of the next-to-last over the last child is not present among other children. Possibly, the full reversal of the birth order effect does not occur for these children until a later age.

In the above data, the firstborns and the second borns are unrelated. Data on first- and second borns from the *same* family would be preferable because these data would not be confounded with extraneous environmental factors such as socioeconomic status. Tabah and Sutter (1954) published an analysis of two-child families based on an earlier French survey (Tabah & Sutter, 1954), and calculations of the scores of firstborns and second borns of different ages can be made directly from their tables. For children who are 9 years old or younger, the second borns are higher in IQ than the firstborns (standard scores of $-.175$ vs. $-.003$ for firstborns and second borns, respectively). For children who are older than 9, the pattern is reversed (.048 vs. .036). This interaction of birth order with age

---

[5] Professor A. Girard, Chief of the Department of Social Psychology. Institut National d'Etudes Démographiques in Paris was kind enough to make some of these data available for the present analysis.

[6] The rising trend of intellectual scores with age results from the manner in which the tests were constructed. Four different forms of the test were prepared. The lowest school grades received only the two most difficult forms, whereas the intermediate grade received various combinations of the other forms. For the purposes of this analysis, however, this overall rising trend can be ignored.

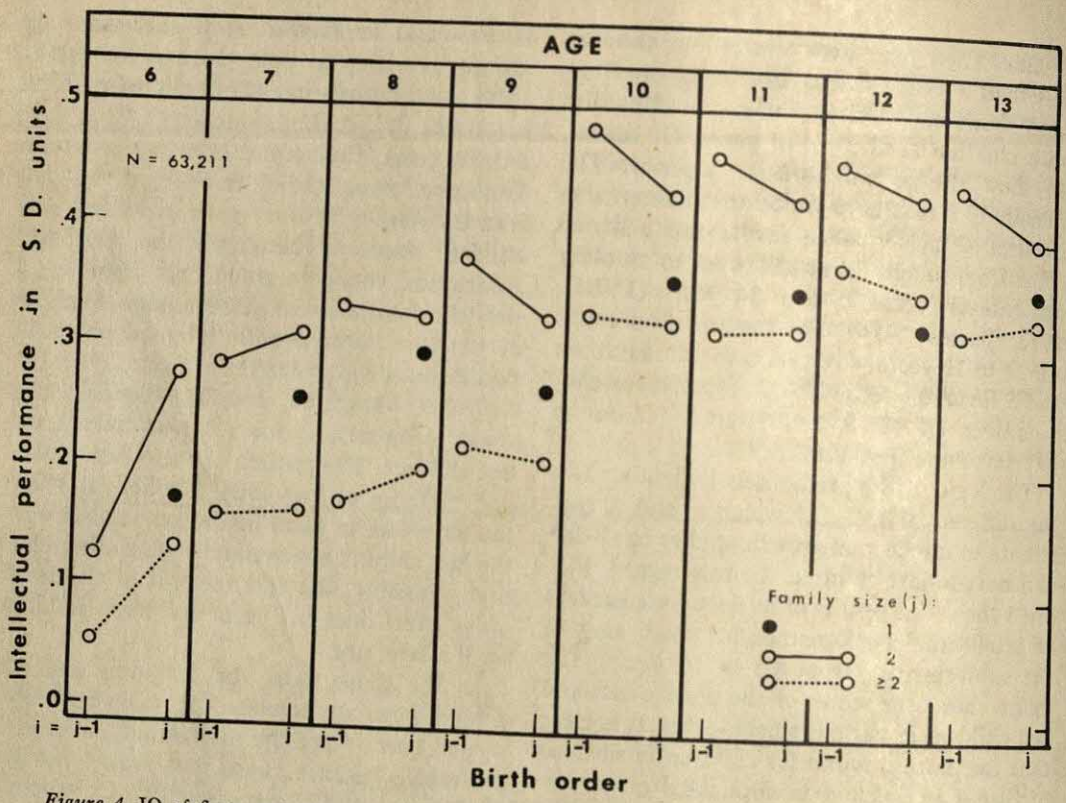

Figure 4. IQ of first- and second borns in families of two and of all next-to-last and last children as a function of age (calculated from data supplied by INED, 1973). S.D. = standard deviation.

is again significant, $F(1, 2476) = 6.65$, $p < .01$.

Conclusions

The predicted effects examined in this article clarify the seemingly conflicting reports on the relationship between birth order and intellectual performance. According to the confluence model, one should not be surprised to find birth order producing positive effects, negative effects, and no effects at all. Such findings, prevalent in the literature on birth order, lead some researchers to regard it as a fruitless field of study. Systematic patterns, however, can now be seen. It has been shown previously (Zajonc, 1976; Zajonc & Markus, 1975) that birth order effects can be better understood by considering the spacing among siblings. In the present article it has been demonstrated that birth order effects are also age dependent. Table 1 shows patterns of results that are entirely consistent with the inferences made from the confluence model. For very young children (i.e., children whose age is less than the typical interval in two-child families) the firstborn surpasses the second born. This advantage is then reversed, and a positive birth order effect prevails from age 3 or 4 years until the early teens. Finally, during the middle teens there is a return to an effect that favors the firstborn and that persists until maturity, and possibly permanently.

This complex pattern of results may be explained by the dynamic interplay between the contributions of the intellectual environment and the child's opportunity to serve as an intellectual resource. Certainly, other factors may contribute to the patterns examined in this article. The age dependence of birth order effects has been noted previously by Cicirelli (1967), who interpreted it as "some sort of trend where at an early age the later born child benefits from the stimulation of an older sibling, and at a later age (where the abstract verbal abilities come into play in the

school situation) the firstborn child profits from his closer exposure to adults" (pp. 482–483). It is also possible that the decline in the growth rate of the firstborn following the birth of a younger sibling may be due to a sudden shift in parental attention and care (Dunn, Note 2). Yet these alternative explanations lead to a variety of implications that are not borne out by the data. The first conjecture would lead us to expect an eventual equalization of performance when the second born reaches the school level, and the second explanation suggests a permanent disadvantage for the older child.

Among other explanations of family size and birth order effects are those couched in biological terms. For example, there is some evidence that perinatal asphyxia-anoxia may produce brain damage in children (Apgar, Girdany, McIntosh, & Taylor, 1955; Campbell, Cheeseman, & Kilpatrick, 1950) and that its incidence increases with parity. Nutritional deficit and hormonal and mineral depletion have also been singled out as factors associated with successive parities and especially with those following each other in close succession (Mertz & Cornatzer, 1971). In general, biological explanations of birth order and family size effects are at present not capable of dealing with the crossovers of the growth rates of only children with first- and second borns, with the crossovers between the siblings of two-child families, and with the crossovers between all last and next-to-last children. That birth order is strictly an environmental factor is strongly suggested by an interesting study of 845 subjects from 120 biological and 104 adoptive families carried out by Scarr and Weinberg (1977). These authors found no differences in birth order effects on IQ when biological and adoptive birth orders were compared. In fact, in a number of regression analyses, the coefficients for biological and adoptive birth order were remarkably similar.

Within the context of the confluence model, it is quite clear that the crossover patterns of growth found in the data cannot be accounted for without assuming some form of facilitation, such as the teaching function, that occurs following the birth of a younger sibling. Thus, both the theory presented here and the confirming data give additional support to the idea that older children do derive some benefit from the presence of a younger sibling.

It must be pointed out that the effects found here are for the most part rather weak. The largest difference in intellectual performance (found between extreme family sizes) is on the order of one standard deviation. Birth order differences are even smaller; differences between adjacent birth ranks are sometimes less than one tenth of a standard deviation. But if these differences had been large and systematic to begin with, the role of family configuration in intellectual development would have been understood long ago.

In a recent article, Grotevant, Scarr, and Weinberg (1977) applied the early outline of the confluence model to individual data and claimed that only 2% of the variance in IQ was accounted for by that version of the model. They concluded that the model was inappropriate for individual data and is useful only for population trends. The 2% of variance that Grotevant et al. found they could explain, however, is not an accurate reflection of what the model can do. Their figures were calculated on the basis of the nonparametrized version of the model and used IQ values rather than mental ages. The predictions, moreover, were made *without allowing* any free parameters whatever and without estimating them from the data. Additional peculiarities in the calculations of Grotevant et al. make their results less than useful in evaluating the performance of the confluence model. Berbaum and Moreland (Note 3) used the current parametrized version of the model (see Appendix) and mental ages as the basis for calculating predicted values in a more recent analysis of individual scores that accounted for nearly half of the variance in the mental ages of 257 children from 51 families.

As we have seen, the present version of the model fits aggregate data quite well, and the previous simpler linear version (Markus & Zajonc, 1977) performed quite well, too. As much as 95% and no less than 88% of the variance can be accounted for with three free parameters when the model is tested on all available large data sets. These predictions

were obtained for a variety of populations from different countries that differ in age, sibling spacing, and socioeconomic background (Zajonc & Bargh, Note 4). Moreover, different data sets involve different measures of intellectual performance. With only two free parameters (k and w_2), as much as 92% and no less than 78% of the variance in aggregate data can be accounted for by the predictions from the model.[7]

The performance of the model evaluated by Berbaum and Moreland (Note 3) must be evaluated against some expectation concerning the amount of variance in IQ that the model *should* explain. If the confluence model were constructed for the particular purpose of accounting for *all* the differences found in IQ —those of genetic origin, those associated with environmental factors, and those resulting from an interaction of these sources—then we would be quite justifiably disappointed in its performance. As much as 25% of the variance in the IQ of children can be attributed to the IQ of their parents alone. However, there is little sound theory *why* as much as 25% of variance in children's IQ is "controlled" by their parents' scores. Some theorists stress genetic factors and use this finding to support a genetic theory of intelligence, others interpret these data as support for an environmental theory, or one that focuses on the correlation and the interaction of these factors (Meredith, 1973). It is to be noted, however, that our analyses that involve cross-sectional aggregate data (that is, all except those in Table 2) have no confounding with genetic factors, since the contribution of parents in these data is held constant at the population average. Within these constraints, the pattern of results reviewed here conforms well to the basic predictions of the confluence model. A more appropriate test requires longitudinal within-family comparisons of cognitive growth, linked with observations of parent–child and child–child interactions. Since the model describes an individual process of intellectual growth, dynamic (temporal) rather than static (cross-sectional) tests are required in verifying its validity. Only repeated observations made at critical intervals on the same individuals can reveal whether the intellectual growth curves manifest the sorts of disturbance, coinciding with the births of younger siblings, that the model predicts. Data of this kind, including the necessary family information and an adequate sample size, are not available. When such research has been carried out, it will illuminate the transmission of environmental effects that emerge in the pattern of individual differences in intelligence described by the extensive literature on family configuration.

[7] For the sake of completeness, a residual factor $\delta_t = w_3\Delta f(t)$, encompassing all influences on intellectual growth not otherwise specified in the model, might also be included. Because this term would reflect all the influences on growth that are extraneous to the home, it could provide useful information. For example, when comparing different subpopulations that have access to different educational or child-rearing resources, comparisons of the relative magnitudes of α and δ might suggest the extent to which intellectual development in these subpopulations reflects factors such as the neighborhood, the school experience, or day-care facilities, for instance, and circumstances strictly related to the home.

Appendix

The Confluence Model: Reparametrized Version

The level of mental maturity, $M_{ij(t)}$, attained at age t by the ith child of j children in a family (see Footnote 1) of n individuals, is expressed as a first-order difference equation

$$M_{ij}(t) = M_{ij(t-1)} + \alpha_t + \lambda_t, \tag{A1}$$

where $t = 1, 2, 3, \ldots$ years. The sum of the two components, α_t and λ_t, both measured at age t, represents the growth increment accumulating each year.

Since intellectual growth is not linear with age, the environmental factors that influence it do not have the same effects at different ages of the child. Thus, the acquisition of a sibling at age 3 years has a more pronounced effect than at age 12, when the child is much nearer intellectual maturity. In the original article (Zajonc & Markus, 1975), we supposed that the effects of family configuration cumulated as a sigmoid function of age, $f(t) = 1 - e^{-k^2t^2}$. The two components α_t and λ_t are therefore expressed as weighted yearly increments of this sigmoid function, $\Delta f(t) = (1 - e^{-k^2t^2}) - (1 - e^{-k^2(t-1)^2}) = e^{-k^2(t-1)^2} - e^{-k^2t^2}$:

$$\alpha_t = w_1 \Delta f(t) [\sum_{i=1}^{n} M^2_{in(t-1)}/n_{(t-1)} + 1]^{\frac{1}{2}}, \tag{A2}$$

and

$$\lambda_t = \frac{w_2 L_t \Delta f(t) \Delta f(\tau)}{(n_t - 1)^2}. \tag{A3}$$

In the above terms, w_1 and w_2 are weights associated with the two components, k is a constant, $f(\tau) = 1 - e^{-k^2\tau^2}$ where τ is the age of the adjacent younger sibling, and L_t is the last-child index, which is equal to 0 for children who at age t are not followed by a younger sibling and is equal to 1 otherwise. The weights w_1 and w_2 represent metric contributions of the component sources of influence upon intellectual growth and need to be estimated from the data. The constant k in $f(t)$ and $f(\tau)$ must also be estimated, and it reflects the rate at which intellectual effects cumulate. It will therefore vary with the population investigated, with the type of ability measured, or with the test employed for its measurement.

In Equation A2 the intellectual environment within the home is represented as a root mean square of the intellectual levels of all family members. This formulation is used, as previously (Markus & Zajonc, 1977), to reflect the greater contribution of the more mature members. Moreover, the denominator is $n + 1$ to allow the quality of the intellectual environment to rise with increasing number of family members. We would not want to consider an environment consisting of one adult to be of the same quality as one consisting of four adults. Thus, for constant values of M, the inequality $nM/(n + 1) < (n + 1)M/(n + 2)$ is always satisfied. It can be readily seen that this formulation of the intellectual environment also reflects the fact that an addition of a new birth will reduce its quality, whereas the addition of an adult will increase that quality.

Cultural Difference in Attribution of Performance: An Integration-Theoretical Analysis

Ramadhar Singh, Meenakshi Gupta, and Ajit K. Dalal
Department of Humanities and Social Sciences
Indian Institute of Technology, Kanpur, India

Heider's suggestion that Performance = Motivation × Ability has been empirically confirmed by Anderson and Butzin and by Kun, Parsons, and Ruble, using American students as subjects. This multiplying process failed to appear in the present series of three experiments performed on Indian college students. Contrary to the predicted linear fan pattern, the plot of Motivation × Ability effect displayed clear parallelism. An equal-weight averaging rule was able to account for the results obtained in both group and single-subject analyses. Perhaps the integration rules underlying achievement judgments are culture-specific, and Indian college students average motivation and ability information in attribution of future scholastic performance. These results illustrate the potential power that information integration theory provides for the cross-cultural study of social perception and cognition.

How do people integrate information about motivation and ability when they predict performance? Heider (1958) made the following suggestion:

> The personal constituents, namely, power (ability) and trying (effort) are related as a multiplicative combination, since the effective personal force (performance) is zero if either of them is zero. For instance, if a person has the ability but does not try at all he will make no progress toward the goal. (p. 83)

If Heider's proposal is correct, then attribution of performance from motivation and ability information would follow the multiplying rule:

$$\text{Performance} = \text{Motivation} \times \text{Ability}. \quad (1)$$

Anderson and Butzin (1974) tested this multiplying rule in two experiments. They presented information about the motivation and ability of target persons, applicants to graduate school and athletes trying out for college track, and asked subjects to predict how the target persons would perform. The factorial plot of the Motivation × Ability judgments was a diverging fan of straight lines. By the logic of functional measurement (Anderson, 1974a, 1976), this linear fan pattern implies the operation of a multiplying rule.

In a developmental study, Kun, Parsons, and Ruble (1974) also obtained evidence for a multiplying rule. Although the youngest children (5–6 years) integrated ability and trying information by an adding-type rule, the linear fan pattern was already present in second graders. The results of these two studies suggest that there is considerable generality to the multiplying rule.

However, an anomalous result appeared

This work was supported by the Research Fund of the Department of Humanities and Social Sciences, Indian Institute of Technology, Kanpur, India. The authors thank K. A. Bohra for his able assistance in data analyses and Norman H. Anderson, H. S. Asthana, John H. Harvey, Lilavati Krishnan, Kent L. Norman, and Jai B. P. Sinha for their comments on an early version of this article. The data reported here were also presented at the 66th annual meeting of the Indian Science Congress Association held at Hyderabad, India, January 1979.

when Anderson and Butzin (1974) presented information about performance and ability and asked subjects to judge motivation. Equation 1 implies a dividing rule,

$$\text{Motivation} = \text{Performance} \div \text{Ability}. \quad (2)$$

However, the data from both experiments supported a subtracting rule,

$$\text{Motivation} = \text{Performance} - \text{Ability}. \quad (3)$$

Anderson and Butzin concluded, therefore, that these judgments obeyed a simple cognitive algebra but that this cognitive algebra was not consistent mathematically.

Perhaps there is an alternative interpretation, one in which the subjects are mathematically consistent. The linear fan pattern is not unique to the multiplying rule. This pattern can also be produced by a conjunctive averaging rule with differential weighting (Anderson, 1971, p. 85). If lower values of motivation and/or ability had greater weight, then the averaging model would produce an approximate linear fan. This conjunctive averaging idea seems reasonable, for it reflects the idea that no amount of motivation can compensate for low ability, contrary to the implications of the multiplying model. This possibility was noted by Anderson and Butzin (1974), who said, "Since averaging processes are pervasive in judgment, a conjunctive integration rule deserves more consideration" (p. 602). However, this possibility has not been considered further.

A test between the multiplying rule and the conjunctive averaging rule can be obtained by asking for judgments based only on ability information. The multiplying rule can only operate if the subject imputes some implicit level of motivation. With this implicit level of motivation, the ability-only curve will still form part of a linear fan. But if the averaging model holds, then the well-known crossover interaction will be observed (Anderson, 1974a; Lampel & Anderson, 1968). No such test was used by Anderson and Butzin (1974) or by Kun et al. (1974).

Experiment 1

Experiment 1 had two purposes. The first was to replicate previous results on the multiplying rule, Performance = Motivation × Ability. The second was to test the plausibility of the alternative interpretation as a conjunctive averaging rule.

Method

Stimuli and design. Sixteen stimulus persons were prepared according to a 4 × 4 design comparable to that of Anderson and Butzin (1974). The two factors were *interest in studies* and *IQ*. The four levels of interest in studies were *slight, less than most, more than most,* and *very high*; the four levels of IQ were 100, 110, 120, and 130. In addition, 4 stimulus persons were described with respect to their IQ alone; their interest in studies was not specified. The information about each of these 20 stimulus persons was typed on a separate sheet of paper, and all 20 sheets were arranged randomly in a booklet.

Four practice examples were also constructed, using stimuli more extreme than the regular levels of the two factors. Levels of interest in studies were *not at all interested* and *extremely interested*; IQ levels were 90 and 140. These practice examples were intended to serve as end anchors and to orient the subjects toward the use of the entire response scale (Anderson, 1974b, Note 1).

Subjects. Subjects were 32 male second-year engineering students enrolled in an introductory psychology course at the Indian Institute of Technology, Kanpur, India. Participation fulfilled a course requirement.

Procedure. Subjects, gathered in groups from three to five, received a typed sheet of instructions that described the nature of the experimental task and their role as subjects. The task was introduced as dealing with prediction of future academic performance of first-year engineering students at the Indian Institute of Technology, Kanpur. It was emphasized that prediction about future performance would be based on interest in studies and intelligence or on intelligence alone. Subjects were instructed to base their prediction only on the information given about each stimulus student.

After reading the instruction sheet twice, each subject worked with the four practice examples. He read the information about each stimulus student and then indicated how that stimulus student would perform at the institute. Prediction of performance was made along a 21-point scale, with endpoints labeled −10 (very bad performance) and +10 (very good performance).

Immediately following the practice period, the main points of the instructions were summarized to the subjects by the experimenter. All queries about the task were answered. Finally, each subject received the experimental booklet and rated all 20 stimulus students twice. In each case, he wrote the code number of the target person and his judgment of performance on the response sheet with the 21-point response scale typed at the top. The first replication

was considered as additional practice, and only the data from the second replication were analyzed.

Results

Figure 1 plots mean judgments as a function of interest in studies (curve parameter) and IQ. The IQ levels are spaced on the horizontal axis according to the marginal means of the factorial design. This spacing allows the linear fan pattern to appear. If the two pieces of information were integrated in accord with the multiplying rule, then the four solid curves would form a diverging fan of straight lines.

It is clear that the pattern of the data is contrary to the multiplying model. There is not any evidence for divergence at all. Instead, the four solid curves display parallelism. This parallelism indicates that subjects integrated the given information by an adding or averaging rule.

The statistical analysis also supported the graphical interpretation. The linear fan pattern predicted by the multiplying model requires a statistically significant Interest in Studies × IQ interaction. However, this interaction was statistically nonsignificant, $F(9, 279) = 1.44$. This result argues against the multiplying model. On the other hand, it supports the parallelism prediction of the adding and averaging models.

A distinguishing test between the adding and averaging models may be obtained by considering the dashed curve in Figure 1. This curve represents judgments based on IQ information alone, with interest in studies not specified. The adding rule requires that the dashed curve be parallel to the solid curves; the averaging rule implies that the dashed curve should have steeper slope than the solid curves (see Anderson, 1974b, Section 3). Visual inspection of Figure 1 thus argues against the adding rule and for the averaging rule.

To obtain a statistical test that would discriminate between adding and averaging, the dashed curve data, which are based on IQ information alone, were considered as a fifth level of the interest-in-studies factor. The interaction term in this 5 × 4, Interest in

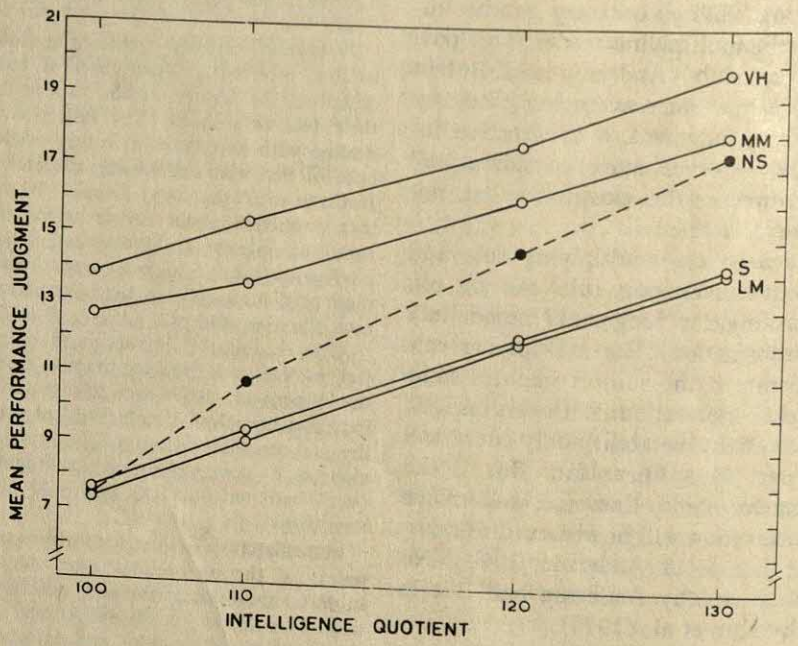

Figure 1. Mean judgment of performance as a function of interest in studies and IQ, Experiment 1. (Levels of *interest in studies* are listed as curve parameters: VH = very high; MM = more than most; LM = less than most; S = slight. The dashed curve is based on IQ information only; interest in studies is not specified [NS].)

Studies × IQ analysis of variance tests for nonparallelism in the set of all five curves in Figure 1. This interaction was highly significant, $F(12, 372) = 8.36$, $p < .01$. Since the four solid curves were essentially parallel, as shown above, it appears that the dashed curve is reliably steeper than the solid curves. This test thus supports the averaging hypothesis and rejects the alternative adding hypothesis.

Discussion

The main result of Experiment 1 is that the information about motivation and ability appears to be integrated by a simple, equal-weight averaging rule. There was no support for the linear fan pattern of the multiplying rule. This result is contrary to the prediction; it disagrees with results from American subjects.

One hypothesis is that this difference in integration rules is a consequence of cultural differences in outlook on social motivation. Before this hypothesis can be taken seriously, however, it is necessary to consider methodological differences between the present and previous experiments.

Methodologically, this experiment was different from those of Anderson and Butzin (1974) in two ways. First, they asked their subjects to describe in writing how they combined motivation and ability cues during the practice session. That was not done in the present work. This difference, however, does not seem to be very serious. Kun et al. (1974) obtained the linear fan pattern with children even without following the Anderson and Butzin procedure. Second, and perhaps more important, the motivation factor was defined here as interest in studies, and the subjects may not have interpreted that in terms of motivation and trying. This possibility was checked in the next experiment by using more explicitly motivational information.

Experiment 2

Experiment 2 was run chiefly as a reliability check on Experiment 1. There were, however, three notable changes from Experiment 1. First, information about laboriousness was used as a motivation cue to allow direct comparison of findings with those obtained in the United States. Second, the levels of the two factors, laboriousness and IQ, were drawn from a wider scale range to increase the opportunity for a linear fan pattern to appear. Finally, sufficient data were gathered from each subject to explore various integration rules on the individual level.

Method

Stimuli and design. A 4 × 4 (Laboriousness × IQ) factorial design was employed to construct 16 two-cue stimulus persons. The levels of laboriousness were *not at all laborious, slightly laborious, fairly laborious,* and *very laborious;* the levels of IQ were 90, 105, 120, and 135. In addition, 8 single-cue stimulus persons were described by one level of either factor.

The practice and filler stimulus persons were described by information more extreme than that used for the regular experimental stimulus persons. For example, laboriousness had *not at all laborious* and *extremely laborious* levels, and IQ had values of 85 and 140. These extreme stimuli were used to orient the subjects toward the use of the entire response scale and also to guard against the operation of floor and ceiling effects as in Experiment 1. Each person description was typed on a separate index card. The eight practice examples included four two-cue and four single-cue descriptions.

Subjects. Subjects were 12 male second-year engineering students fulfilling a course requirement in elementary psychology at the Indian Institute of Technology, Kanpur, India. Two subjects were run at a time in a session that lasted approximately 1.5 hours.

Procedure. The general procedure was the same as in Experiment 1 except that subjects read the entire set of descriptions before beginning their actual judgments. The complete set of 24 experimental and 2 filler descriptions was presented three times in different shuffled order for each subject. Data from all the three replications were analyzed.

Results

Parallelism prediction. The upper left panel of Figure 2 plots mean performance as a function of laboriousness (curve parameter) and IQ (horizontal axis) of the stimulus persons. If the result obtained in Experiment 1 is reliable, then the four solid curves should plot as parallel lines. Inspection shows that these curves are essentially parallel. The Laboriousness × IQ interaction in the 4 × 4 design was, however, significant, $F(9, 99) = 2.13$, $p < .05$. This corresponds to a slight tendency for the four curves to converge to the right. There is no sign of the diverging linear fan pattern reported in the American studies. Despite the

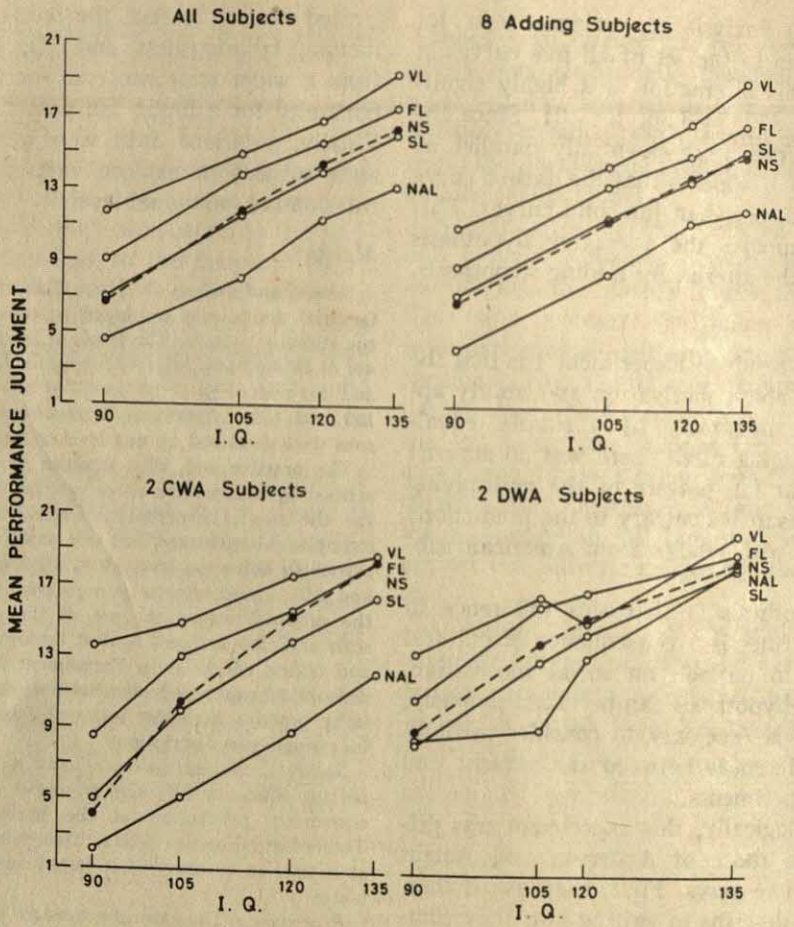

Figure 2. Mean judgment of performance as a function of laboriousness and IQ, Experiment 2. (Levels of *laboriousness* are listed as curve parameters: NAL = not at all laborious; SL = slightly laborious; FL = fairly laborious; VL = very laborious; NS = laboriousness not specified. Classification of subjects into adding, constant-weight averaging [CWA], and differential-weight averaging [DWA] subgroups was based on results from single-subject analyses.)

change in the nature of the motivation information, these results confirm those of the first experiment.

Averaging versus adding. The dashed curve in the upper panel of Figure 2 represents judgments based on IQ alone, with no information about laboriousness. This curve is nearly parallel to the solid curves. At face value, this seems to argue for the adding hypothesis and against the averaging hypothesis. The result raises some difficulty for both hypotheses, however.

The difficulty with the adding hypothesis is that the dashed curve has the same elevation as the solid curve for *slightly laborious*. Under the adding hypothesis, this equality in elevation requires that information that the student is slightly laborious has the same effect as lack of information about laboriousness. If *slightly laborious* has a value of zero, then of course there is no problem. However, if *slightly laborious* has a value different from zero, then *lack of information* must have the same value. In this case, therefore, it would be necessary to assume that the subject infers an implicit level of laboriousness when no explicit information is given and that he adds this value to the other information given.

The difficulty with the averaging model is the failure of the dashed curve to cross over the solid curve. However, the averaging model can account for the near-parallelism if it is

assumed that subjects infer an implicit value of laboriousness when no information is given and that they average that in with the other given information. If this inferred implicit value has the same weight as given laboriousness information, then the corresponding dashed curve will be parallel to the solid curves.

The assumption that subjects infer an implicit value for missing information about laboriousness seems reasonable for the present task. Logically, a prediction of performance cannot be made on the basis of IQ information alone; some information pertaining to degree of laboriousness is necessary. This question cannot be decided on the basis of the above data, but some evidence is available from Experiment 3.

Single-subject analyses. Separate analyses were made for each subject (Shanteau & Anderson, 1969, p. 315) to find out the various ways in which the experimental task was handled and also to explain the minor discrepancy from parallelism in the main analysis mentioned earlier. In these analyses, the subjects were broken down into three subgroups.

Mean performance judgments for these three subgroups of subjects are shown in Figure 2. The upper right panel displays results for eight subjects, all of whom showed nonsignificant interactions. Here parallelism is quite obvious. Perhaps these subjects followed an adding or an averaging rule. The lower left panel plots data from two subjects who apparently averaged, as shown by the crossover of the dashed and solid curves. The lower right panel shows two subjects who had a strong convergence tendency. However, the general shape of the curves is too irregular to be interpreted.

The most important information from these individual analyses is that not a single subject showed the diverging fan pattern obtained in the American studies. That supports the suggestion of Experiment 1 that Indian subjects make achievement judgments in a rather different way from their American counterparts.

Discussion

The parallelism pattern observed in Experiment 1 is replicated here. Although information about laboriousness, rather than interest in studies, served as the motivation factor, and although the laboriousness and IQ factors had levels from a wider range than in Experiment 1, the findings are basically identical. Most of the subjects obeyed the parallelism prediction. More importantly, not even one subject showed a diverging fan pattern predicted by the multiplying-type strategy. These results support the hypothesis that the differences between the American and Indian studies result from cultural differences.

The findings of the first and second experiments converge to make a single point: Information about motivation and ability is added or averaged in making attributions of future scholastic performance. The evidence leans toward the averaging hypothesis, but the results of Experiment 2 require the supplementary assumption that the subject imputes an implicit value for motivation when no information is given. This assumption is reasonable, since no performance is logically possible without some level of motivation. Nevertheless, more direct evidence is required.

Direct evidence can be obtained by using three stimulus cues. If the averaging model is correct, then the single-cue curves should be clearly steeper than the curves in the two-way factorial plots from the three-cue design. The reason for this is simple. When the single cue is given, any implicit inference about the absent motivation information will yield an effective two-cue response. But the averaging model implies that the slope of a curve based on two cues will be greater than that based on three cues. Accordingly, the crossover test remains valid even if the subject does impute an implicit value to the missing dimension of information. The adding hypothesis, of course, still predicts parallelism in such a three-cue design.

Experiment 3

Experiment 3 had two goals. The first was to extend the findings of Experiment 2 by including a third informational cue about past performance. The second was to resolve the ambiguity in the test of the averaging model in Experiment 2.

Method

Stimuli and design. There were two main designs. The first design was a 3 × 3 × 3 (Past Performance × Laboriousness × IQ) factorial. The three levels of past performance were Cumulative Performance Index (CPI) of 5, 7, and 9 during the first year of study at the Indian Institute of Technology, Kanpur. This information was from a 10-point scale. The three levels of laboriousness were *not at all laborious, fairly laborious,* and *very laborious;* the three levels of IQ were 90, 112, and 135. Orthogonal combinations of these three factors generated 27 three-cue stimulus persons.

The second design was a 3 × 3 (Laboriousness × IQ) factorial. The levels of laboriousness and IQ factors were the same as in the three-cue design. Pairing of the levels of these two factors produced nine two-cue stimulus persons.

There were also 9 single-cue stimulus persons, based on one of the three levels of each factor. In addition, 4 three-cue filler persons were constructed to serve as end anchors. All these 49 stimulus persons, including the 4 filler persons, were judged by each subject.

Procedure and subjects. The general procedure was the same as in Experiment 2. Each subject rated 49 stimulus persons three times. As in Experiment 2, a description of each stimulus person was typed on a separate index card.

Before rating the experimental stimuli, each subject worked with 10 practice examples prepared from extreme levels of the informational factors. Of the 10 examples, 4 had three cues, two had two cues, and the remaining four had just one cue.

There were 12 subjects from the same population as in Experiment 2. Two subjects were run at a time. Each subject spent approximately 2.5 hours on the task.

Results and Discussion

Three-cue design. The main purpose of Experiment 3 was to study the integration rule for the three cues. On the basis of their results, Anderson and Butzin (1974) suggested the compound averaging-multiplying rule:

$$\text{Predicted Performance} = \text{Past Performance} + \text{Motivation} \times \text{Ability}. \quad (4)$$

However, the results of the present Experiments 1 and 2 suggest the three-term averaging rule:

$$\text{Predicted Performance} = \text{Past Performance} + \text{Laboriousness} + \text{Ability}. \quad (5)$$

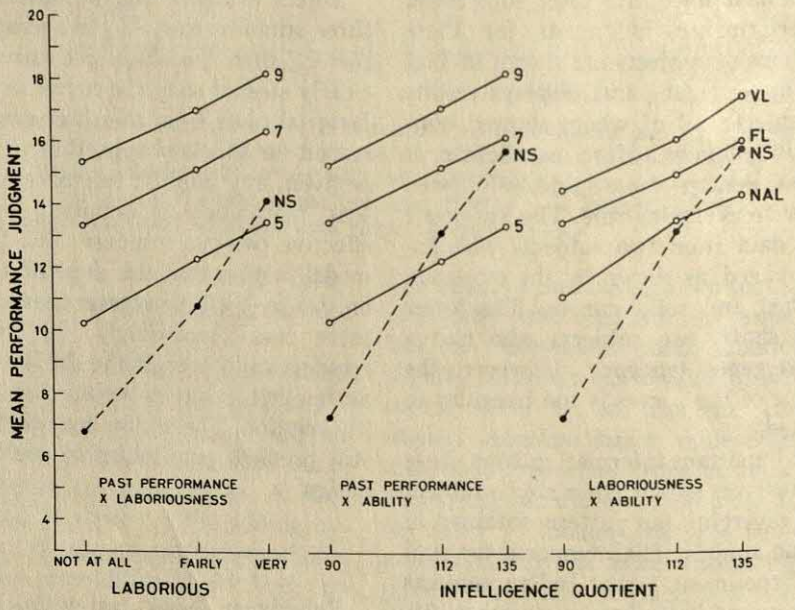

Figure 3. Two-way factorial plots of Past Performance × Laboriousness, Past Performance × Ability, and Laboriousness × Ability effects from the main three-cue, Past Performance × Laboriousness × Ability design. (The dashed curve of each panel is based on the single cue listed on the horizontal axis. Digits 5, 7, and 9 represent levels of past performance; NAL, FL, and VL represent *not at all laborious, fairly laborious,* and *very laborious,* respectively. NS means that the row information was not specified.)

The results of Figure 3 support the three-term averaging rule. Each panel shows one of the two-cue factorial graphs from the main design. In each panel, the solid curves are approximately parallel. The right panel, which corresponds to the Laboriousness × Ability interaction, is marginally significant, $F(4, 44) = 2.46$. However, the three solid curves show a slight convergence, as in Experiments 1 and 2, not the divergence predicted by the multiplying rule.

A test between the adding and averaging rules is obtained by comparing the dashed curve with the solid curves in each panel of Figure 3. The dashed curve represents judgments based on just the single cue listed on the horizontal axis. In each panel, the dashed curve has much steeper slope and crosses over the lowest solid curve convincingly. This crossover interaction is evidence against the adding rule and supports the averaging rule.

Two-cue design. The two-cue design was included to provide a further check on the two-cue results of Experiments 1 and 2. These data are shown in Figure 4. The solid curves are approximately parallel, but with a visible and barely significant tendency to converge to the right, $F(4, 44) = 2.85$, $p < .05$. The dashed curve is again nearly parallel to but slightly steeper than the solid curves. These results are essentially the same as those in Experiment 2.

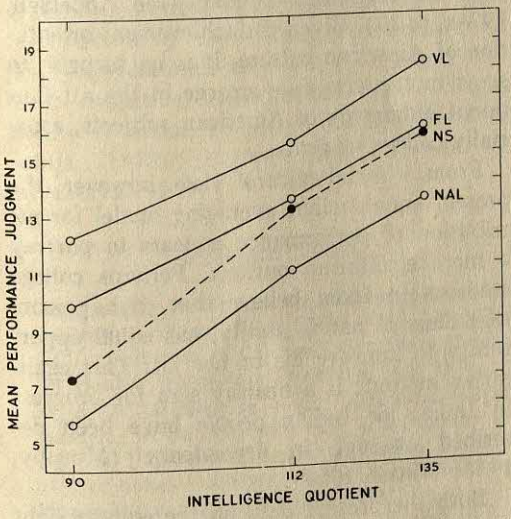

Figure 4. Mean judgment of performance as a function of *laboriousness* and IQ, Experiment 3, two-cue design. (NAL, FL, and VL represent *not at all laborious, fairly laborious,* and *very laborious,* respectively. NS means that the row information was not specified.)

Table 1
F *Ratios for Two-Way and Three-Way Interactions in Single-Subject Analyses (Experiment 3, Three-Cue Design)*

Subject	AB $F(4, 52)$	AC $F(4, 52)$	BC $F(4, 52)$	ABC $F(8, 52)$
1	2.69*	.58	.94	.84
2	2.23	3.33*	1.28	1.79
3	1.64	.74	1.77	.98
4	.84	1.19	3.73*	1.41
5	1.72	1.14	1.22	.87
6	.78	1.15	.77	.53
7	.35	.59	.95	.93
8	2.75*	1.09	1.18	3.50*
9	.42	.16	.91	.75
10	.51	.23	1.29	.91
11	1.36	.51	1.73	.27
12	1.65	.76	1.32	.68

Note. A = Past performance. B = Laboriousness. C = IQ.
* $p < .05$.

These two-cue data support the assumption of implicit inference about absent motivation information discussed in Experiment 2. The dashed curve in the center and right panels of Figure 3 is the same as the dashed curve of Figure 4. The clear crossover of the dashed curve in Figure 3 supports the averaging rule. Hence, the failure to obtain a clear crossover in Figure 4 would seem to reflect the presence of an inferred, implicit value for the missing motivation cue.

Single-subject analyses. As Shanteau and Anderson (1969) emphasized, individual analyses are important to check that the group averages are not hiding alternative integration strategies by different subjects. Table 1 presents the F ratios for the four interactions for each subject in the main three-cue design.

Table 1 shows that only five scattered interactions are statistically significant. Inspection of individual data failed to disclose any meaningful pattern to these deviations from parallelism. Instead, these deviations seemed to reflect individual idiosyncracies such as may be seen in the lower right panel of Figure 2. Almost all individuals showed the crossover

interaction for the single cue curves. Thus, the present results support the generality of the averaging rule at the level of the individual.

In single subject analyses of the two-cue, Laboriousness × IQ data, 11 of the 12 subjects showed parallelism. Only 1 subject had a converging type of nonparallelism. It can thus be said that present two-cue results are indeed similar to those of Experiments 1 and 2.

General Discussion

The results of the present set of three experiments do not agree with the multiplying model suggested by Heider (1958) and tested by Anderson and Butzin (1974) and by Kun et al. (1974). In the present experiments, attribution of performance from motivation and ability cues appears to have been governed by a process quite different from the multiplying. Strong evidence for parallelism pattern indicates that an equal-weight averaging rule could very well account for the data. It seems reasonable to suggest, therefore, that attribution of scholastic performance obeys an averaging rule in India.

Collateral work by Singh (Note 2) helps solidify this cultural-difference interpretation of the present results. Singh presented information about generosity and income of various persons and asked subjects to predict how much these persons would contribute to a family whose house had burned down. This experiment parallels that of Graesser and Anderson (1974) on Gift Size = Generosity × Income, and quite similar results were obtained. Judgments of gift size showed a diverging fan pattern, as if a multiplying model was operative, just as in the American studies. This shows that the present Indian subjects are able to use the same integration rule as the Americans. Accordingly, their present use of an equal-weight averaging rule would not seem to be attributable to the subjects' inappropriate understanding of the task, their attempt to simplify it (Anderson & Butzin, 1974), or their inability to use the same integration rule as the Americans. It can thus be said that the present discrepancy from the American results reflects a difference in cultural outlook.

Does the difference between the equal-weight averaging rule and the multiplying rule point to any important difference in cultural outlook between India and America? For attributions of achievement, given information about motivation and ability, the following argument suggests at least one important social difference. According to the equal-weight averaging model, effort or trying will be equally effective with persons of low or high ability. Within a cultural system of attributions that obeys the averaging model, therefore, it will appear that a person of lower ability can gain as much by trying as a person of higher ability.

The multiplying rule, in contrast, implies that effort or trying will be more effective with persons of higher ability. Within a cultural system of attributions that obeys the multiplying rule, therefore, it will appear that persons of lower ability have less to gain by trying.

This multiplying rule for attributions may be closer to the actual behavior processes, since just such a rule is found in most current behavioral theories of motivation, such as those of Hull and Tolman (see Anderson, 1974a, p. 29). Given the achievement orientation of American culture, it is no surprise to see a multiplying rule emerge in the attributional judgments of American subjects, especially college students.

From a social-cultural view, however, the present equal-weight averaging model for attribution of performance appears to portray a more egalitarian outlook. Perhaps college students in India believe that each person, regardless of native ability, has equal opportunity to improve his or her lot. This egalitarian attitude is a healthy sign for progress in India, for Indian people have been described as high in dependency (Murphy, 1953; Winter, 1969).

Both the present data on the equal-weight averaging rule and the previous American results on the multiplying rule, however, rest on a very narrow cultural sample, namely, college students. If the cognitive algebra of achievement attribution is to be useful in

cross-cultural research, then it is necessary to study many other cultural strata, both in India and in the United States.

To the authors, information integration theory is impressive because it provides a useful framework for cross-cultural studies of social perception and cognition. An important characteristic of the integration rules, it should be emphasized, is that they are concerned with *patterns* of responses, not with the numerical value of single responses. This characteristic is vital for cross-cultural comparisons because it bypasses uncertain assumptions that specific stimuli have comparable values across cultures. Indians and Americans undoubtedly have different value systems, but they can still be compared in terms of the pattern of their responses to a factorial set of stimuli. Indeed, the integration rule can provide a base and frame for measurement of meaning–value even for the individual within his or her culture (Anderson, 1976, 1977). The present results illustrate the potential power of this approach.

Because of its direct concern with the problems of multiple causation, integration theory is well suited for cross-cultural comparison. Of special interest and value is that the integration-theoretical approach can help shift the direction of cross-cultural research from a purely correlational approach (Whiting, 1968) to a causative, experimental base (Singh, Bohra, & Dalal, in press; Singh, Sidana, & Saluja, 1978a, 1978b; Singh, Sidana, & Srivastava 1978).

The Effects of Reward Contingency and Performance Feedback on Intrinsic Motivation

Judith M. Harackiewicz
Harvard University

In this study the effects of reward contingency and positive performance feedback on subsequent intrinsic motivation for an enjoyable task were examined. It was hypothesized that rewards contingent only upon participation in the task would produce decrements in motivation (the overjustification effect) but that rewards contingent on performance quality would produce even greater decrements in intrinsic motivation relative to control conditions of no reward. It was also hypothesized that positive performance feedback would enhance intrinsic motivation and that this effect would be independent of reward effects. High school students were offered performance or task-contingent rewards, or no reward, for doing hidden-figures puzzles. Subjects offered performance-contingent rewards all received positive feedback concerning performance and half the subjects in task-contingent and no-reward conditions received the same positive feedback. Performance-contingent rewards were found to undermine intrinsic motivation more than task-contingent ones, which produced decrements relative to control conditions of no reward, supporting Deci's control model. Positive feedback enhanced intrinsic motivation and this effect was independent of reward effects. A recall measure indicated that subjects receiving performance-contingent rewards remembered fewer performance-irrelevant details about the task, suggesting that rewards may affect the process of task involvement as well as its motivational outcomes.

In a review of the literature concerned with the effects of extrinsic rewards on intrinsic motivation, Condry (1977) concludes that in certain contexts, subsequent interest in a task may be reduced by the imposition of task-extrinsic rewards. One aspect of context that apparently mediates this undermining effect is reward contingency. Rewards have been promised to subjects contingent only upon participation or for completion of the task (task contingent),[1] or contingent upon some level of performance of the task (performance contingent).

The undermining effects of task-contingent rewards have been well documented (Anderson, Manoogian, & Reznick, 1976; Lepper, Greene, & Nisbett, 1973). Rewards promised to subjects for engaging in an activity and implying no performance demands have consistently produced what Lepper and Greene (1976) termed the "overjustification effect,"

The author thanks John Kihlstrom, Bella DePaulo, Reid Hastie, and Robert Rosenthal for their help with the planning of this research and the data analysis, and Mark Lepper, Michael Ross, and Shelley Taylor for helpful comments on earlier versions of this article. I am grateful to Harold Rosen, Mary Harackiewicz, and Cliff Thurber for their cooperation and assistance in collecting the data. I would also like to thank Al Hirschfeld and the Margo Feiden Galleries for permission to use his drawings in this research.

Requests for reprints should be sent to Judith Harackiewicz, Department of Psychology and Social Relations, Harvard University, 33 Kirkland Street, Cambridge, Massachusetts 02138.

[1] These rewards have frequently been referred to as *noncontingent* rewards. Although not explicitly contingent on some level of performance, they are usually at least implicitly contingent on compliance with the experimenter or participation in the activity and are perhaps more appropriately considered task contingent.

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3708-1352$00.75

or a decrease in subsequent intrinsic motivation. Their most recent theoretical statement specifies the context in which this effect should occur:

> The overjustification studies provide a demonstration of the negative effects on intrinsic motivation of making salient to a person the instrumentality of his behavior when rewards are presented which do not result in the acquisition of new skills or convey salient information to him concerning his ability at a task. (Lepper & Greene, 1976, p. 33)

Because the promise of a performance-contingent reward implies that information concerning task ability will be provided, specific predictions for the effects of performance-contingent rewards cannot be directly derived from the overjustification hypothesis. Other investigators, however, have attempted to examine the effects of such rewards and to relate them to overjustification effects. Two predictions for performance-contingent rewards have been advanced. Karniol and Ross (1977) suggested that performance-contingent rewards may maintain or increase intrinsic motivation to the extent that they convey information about effective performance at a task, because attainment of such rewards should provide tangible evidence of personal effectiveness. Deci (1975), on the other hand, predicted that a performance-contingent reward should decrease intrinsic motivation even more than a task-contingent one because a reward is perceived to be more controlling when it is contingent on some level of performance.

Karniol and Ross and Deci agreed that rewards have controlling and informational aspects, and both suggested that the more salient of the two will initiate either changes in perceptions of instrumentality of behavior (when controlling aspects of the reward are salient) or changes in feelings of competence and self-determination (when informational aspects are salient). Their predictions for the effects of performance-contingent rewards differed because of differences in the ascribed salience of controlling versus informational aspects of these rewards.

Previous Research

Deci (1971, 1972a) consistently found that subjects receiving performance-contingent rewards demonstrate less subsequent intrinsic motivation than unrewarded controls. Pritchard, Campbell, and Campbell (1977) and Pittman, Cooper, and Smith (1977) found that performance-contingent rewards undermined intrinsic motivation relative to control conditions of no reward. Pinder (1976) found that performance-contingent rewards produced greater decrements in intrinsic motivation than did task-contingent ones. Although these results all seem to disconfirm the hypothesis of Karniol and Ross, the studies do not represent adequate tests of it, because performance-contingent rewards are predicted to maintain interest only when subjects perceive that they have done well at the task. It is not clear that this criterion was met in these studies.

Two studies have compared task-contingent and performance-contingent rewards with a control condition of no reward in the same design. Greene and Lepper (1974) found that performance and task-contingent rewards produced equal decrements in intrinsic motivation relative to control conditions. Karniol and Ross (1977) found that when children received positive feedback concerning their performance, task-contingent rewards decreased subsequent interest relative to performance-contingent rewards and no rewards. Performance-contingent rewards did maintain interest, but they did not increase it above the control level as had been predicted. Karniol and Ross suggested that because the performance standard was established in the reward manipulation at the outset, children knew that they had performed well as soon as they finished the task. The information inherent in the receipt of the reward was thus redundant with that provided in the instructions. The researchers predicted that when the receipt of a reward provides additional rather than redundant information concerning competence, it should increase intrinsic motivation above the level of control subjects.

Methodological Issues

One aspect of reward contingency that has not been directly examined is the possible confounding of material reward with positive

feedback about performance quality. The promise of a performance-contingent reward implies that a subject's performance will be evaluated and that feedback will be available. Deci (1972b) and Anderson et al. (1976) demonstrated that positive feedback, in the absence of any reward manipulation, increases subsequent intrinsic motivation. Although it is difficult to separate reward manipulation from feedback in the case of performance-contingent rewards, it is possible to examine the effects of reward and feedback independently in task-contingent and control conditions because feedback is not implied by a task-contingent reward manipulation.

Several measures of intrinsic motivation have been used in the overjustification literature, ranging from behavioral measures (task persistence in the absence of rewards) to volunteering measures (willingness to return for another session) to self-report measures of task interest and enjoyment. Conflicting results of previous studies may be due to different operational definitions of intrinsic motivation.

Condry (1977) draws a distinction between dependent measures that focus on the products of the rewarded session, for example, subsequent interest, and measures that focus on the process of task involvement, and he suggests that the promise of extrinsic rewards may affect the manner in which subjects engage in a task, as well as subsequent motivation. Products and processes may be differentially affected by rewards, however, and should be considered separately.

Objectives

The primary aim of the present study was to examine the effects of performance- and task-contingent rewards on intrinsic motivation, compared to conditions of no reward. To accomplish this, two kinds of performance-contingent rewards were created. A performance-contingent reward with performance norms supplied at the outset of the task would convey no additional information concerning competence beyond that inherent in the norms. A performance-contingent reward with no prior norms established would provide nonredundant information concerning competence. These two performance-contingent rewards were compared with task-contingent rewards and control conditions of no reward. In addition, the effects of positive performance feedback, relative to no feedback, were examined in conditions of task-contingent and no reward in order that results might be comparable to both those of Karniol and Ross and those of other studies that have demonstrated the undermining effects of task-contingent rewards in the absence of positive performance feedback.

To facilitate comparison with other studies, several behavioral, volunteering, and self-report product measures of intrinsic motivation were utilized. Interest was measured at several points in time in order to examine the endurance of reward effects. The task in this study was constructed in such a way that attention to aspects of it not relevant to performance could be measured with an incidental recall measure, intended to assess the process of intrinsic motivation.

It was predicted that positive feedback would enhance intrinsic motivation, that task-contingent rewards would undermine it, and that these two effects would be independent. The effects of performance-contingent rewards were of particular interest because of conflicting predictions: an enhancement of motivation mediated by perceived self-efficacy (Karniol & Ross, 1977) or a detrimental effect because of the perceived controlling nature of the reward (Deci, 1975). Controlling the informational value of the reward permits closer analysis of performance-contingent rewards. Karniol and Ross predict that the more informational performance-contingent reward with no prior norms established should produce the most enhancement of motivation. Although Deci does not make specific predictions regarding informational value, a speculative control prediction was generated. Because the two rewards are both contingent on performance quality, equal decrements might be predicted, but this negative effect could be differentially mitigated by the two types of positive feedback. When norms are supplied at the outset, the feedback is received earlier in the motivational process and might have a

greater positive effect than would feedback received after completion of the task. According to this analysis, the control hypothesis would produce a larger decrement in interest in the performance-contingent condition where norms are not supplied. It was hypothesized that the control prediction would be supported in this study because of the greater similarity of the subject population (high school students) to Deci's college students than to the children used as subjects by Karniol and Ross.

Method

Overview

In this study six groups of subjects received various combinations of reward and positive feedback with respect to a challenging but enjoyable task. Interest in this task was assessed both before and after the experimental manipulations. The six experimental conditions are summarized in Table 1. The no reward – no feedback (NRNF) and task-contingent reward – no feedback (TCRNF) cells replicate the conditions employed in overjustification studies, whereas the no reward – positive feedback (NRPF), task-contingent reward – positive feedback (TCRPF) and performance-contingent reward (norms supplied) – positive feedback (PCRNSPF) cells are conceptual replications of the central features of the Karniol and Ross (1977) design. Subjects in the PCRNSPF condition were offered a reward contingent on performing above average and were informed of the performance standard before beginning the task, so that receipt of the reward only confirmed that they had performed above average. In the performance-contingent reward (no norms) – positive feedback (PCRNNPF) condition, however, the reward itself was the only source of information available to the subject concerning level of performance. Thus the reward received in the PCRNNPF condition was more informational than that received in the PCRNSPF condition, although subjects in both conditions received the same feedback concerning performance. The standard of performance was set at a relatively low level so that all subjects would be eligible for positive feedback.

Subjects

The participants in this study were 64 male and 29 female students in a suburban Massachusetts high school, with a mean age of 16.4 years. The subjects were tested during their English class.

Procedure

The study was conducted in three phases. The first and third sessions were group administered in the classroom, whereas subjects were tested individually in a separate room for the second session. This experimental session began 1 month after the first session and continued for 2 weeks, and the third session took place 1 month after the end of the experimental sessions.

The experimental activity in this study was a series of hidden-figure puzzles—cartoon-style drawings by Al Hirschfeld, in which the name *Nina* is hidden sev-

Table 1
Schematic Design of Experiment and Contrast Weights for Main Hypothesis

Condition	Reward	Feedback	Contrast weight
No reward–no feedback (NRNF)	None mentioned	None	1
No reward–positive feedback (NRPF)	None mentioned	Positive[a]	3
Task-contingent reward–no feedback (TCRNF)	Offered for doing puzzles	None	−1
Task-contingent reward–positive feedback (TGRPF)	Offered for doing puzzles	Positive[a]	1
Performance-contingent reward (norms supplied)–positive feedback (PCRNSPF)	Offered for meeting performance criterion, norms supplied before task	Positive[a]	−1
Performance-contingent reward (no norms)–positive feedback (PCRNNPF)	Offered for meeting performance criterion, no norms supplied	Positive[a]	−3

[a] Positive feedback was "We've found that the average student usually finds 4 Ninas, so you did better than the average high school student on these puzzles."

Figure 1. A Nina puzzle (Hirschfeld's drawing for the play *Anna Christie,* © courtesy of the Margo Feiden Galleries, New York, New York).

eral times. These drawings appear in the Arts and Leisure section of the Sunday *New York Times* and are usually caricatures of actors and scenes from current films and plays. Each drawing has a title and a caption describing the scene and naming the actors depicted. The drawings used in this study contained three to seven hidden Ninas. An example of a Nina puzzle (in which there are seven hidden Ninas) is shown in Figure 1.

Pretest. The students were given booklets containing three kinds of puzzles. The word puzzles consisted of several anagrams; the face and body recognition puzzle was the booklet form of the Profile of Nonverbal Sensitivity (PONS; Rosenthal, Hall, DiMatteo, Rogers, & Archer, 1979), which consists of 40 pictures of a face or body and two brief situation labels from which the subject selects the more appropriate description of the picture; there were also three Nina puzzles. The order in which students did the three puzzle sets was counterbalanced. After doing each puzzle set, students completed a puzzle questionnaire that consisted of 13 7-point bipolar

rating scales (e.g., good–bad, easy–hard, boring–exciting) and eight questions concerning the subject's involvement with the puzzle (e.g., "How much did you enjoy the puzzle?"), also answered on 7-point scales. After completing all three types of puzzles, the students rank ordered them according to enjoyment.

Experimental session. The experimenter informed each subject that he or she would be doing more Nina puzzles and that the instructions were tape recorded. After turning on the tape recorder she left the room in order to remain blind to the subject's condition, which was randomly determined. All subjects were instructed to find as many Ninas as possible within the 2 minutes of inspection time allowed per drawing. Subjects in the two task-contingent reward conditions (TCRNF and TCRPF) were promised a reward for doing the puzzles, whereas subjects in the two performance-contingent reward conditions (PCRNSPF and PCRNNPF) were promised a reward for exceeding the performance of the average high school student. Those in the performance-contingent reward (norms supplied) – positive feedback group were then informed of the exact performance standard (detecting four or more Ninas in the three puzzles combined). All subjects who had been promised a reward (TCRNF, TCRPF, PCRNSPF, and PCRNNPF) were told that it consisted of two felt-tip pens and a notebook, in their choice of colors, and were reminded of the conditions of the reward. Finally, the subjects completed an identification form and answered a series of questions concerning their understanding of the directions, the reward contingencies, their current mood state, expected puzzle difficulty and performance level, and attitude toward the reward.

The experimenter returned to the room and administered the three Nina puzzles. Subjects in the NRPF, TCRPF, PCRNSPF, and PCRNNPF groups then received positive performance feedback ("We've found that the average high school student usually finds four Ninas, so you did better than the average student on these puzzles"), and those who were promised a reward (TCRNF, TCRPF, PCRNSPF, and PCRNNPF) indicated their color choices on forms that again reminded them of the conditions under which the reward had been promised. The experimenter was blind to this latter information. While the experimenter filed away the puzzles and order forms, the subject was permitted to read a current popular magazine, work on another Nina puzzle, or simply sit quietly. The experimenter unobtrusively observed the subject's behavior and recorded the amount of time spent on the puzzle, if any.

After 2 minutes the subject completed several questionnaires, including a Nina puzzle questionnaire identical to the one administered at the pretest. A volunteering questionnaire stated that although there were no definite plans for future sessions, the researcher wanted a general idea of student willingness to return. It was composed of four 7-point rating scales asking the subject how willing he or she would be to return for a further, unrewarded session of Nina puzzles if it were scheduled during their English class, during a study hall, after school, or on a weekend. The extra puzzles request form informed subjects that copies of different Nina puzzles would be available after the conclusion of the research and permitted students to request up to four additional puzzles. The recall questionnaire was composed of a list of actors, in which were embedded the names of those depicted in the Nina puzzles from the experimental session, and a similar list of play and film titles; students were asked to circle any names that they remembered seeing in the puzzles.

If the subject had not previously been offered a reward, he or she was informed at this time that there was a gift for having participated in psychological research. These subjects then indicated their color choice for the pens and notebook on an order form that reminded the subject of the rationale for the gift.

Finally, all subjects were assured that the experiment would be explained to them in detail when the rewards/gifts were delivered at its conclusion. They were also cautioned not to discuss the details of the experiment with other students.

Posttest. One month after all students had participated in the experimental session, their teacher distributed a letter from the experimenter saying that she would be visiting their classroom soon with deliveries and to answer questions about the research project. At this time they completed yet a third Nina puzzle questionnaire.

The experimenter visited the classroom a few days after the students received the letter, distributed the rewards/gifts (and extra puzzles if requested), and debriefed the students.

Dependent Measures

In addition to various manipulation checks concerned with the informational effects of positive feedback and postmanipulation motivation, several dependent variables were of interest in this study. Performance was indexed by the number of Ninas actually found on the three puzzles administered during the experimental session; all subjects found at least 4 Ninas, and no subject found all 15 contained in the drawings. Initial levels of intrinsic motivation were indexed by a pretest enjoyment scale derived from the pretest Nina puzzle questionnaire in the manner described below.

There were five outcome measures of intrinsic motivation taken after the experimental manipulation: (a) *experimental enjoyment*—a scale identical to the pretest enjoyment scale, but administered after the experimental task; (b) *time*—the amount of time that the subject spent looking at the extra Nina puzzle during the free-choice period; (c) *volunteering*—score on the volunteering questionnaire; (d) *extra puzzles*—the number of puzzles requested by the subject on the extra puzzles request form; and (e) *posttest enjoyment*—a scale identical to the pretest and experimental enjoyment scales, but administered dur-

ing the posttest.[2] A further measure was a process variable intended to index the level of task orientation during the experimental session: (f) *incidental recall*—the number of names and titles correctly recognized on the recall questionnaire, corrected for overcircling by subtracting one half the number of incorrect answers.

Results

Pretest Analyses

A principal-components factor analysis with varimax rotations was performed on the 21 items of the Nina puzzle questionnaire, and the first factor extracted accounted for 50.6% of the variance. Seven items had factor loadings higher than .70 and were considered to contribute to the definition of the factor: Enjoyable, Good, Interesting, Exciting, Enjoyment of Puzzle, Interest in Puzzle, and Worthwhile. This factor was interpreted independently by two judges to measure task enjoyment, and scores on each of the 7 items were combined using unit weighting to form an enjoyment scale. Pretest enjoyment was used as a covariate in subsequent analyses of covariance.

Since the overjustification effect is predicted to occur only when intrinsic motivation for an activity is initially high (Lepper & Greene, 1976) it is necessary to establish that the Nina puzzles were in fact intrinsically interesting. The mean score for pretest enjoyment was 33.98 ($SD = 9.20$); this was significantly higher than 25, the midpoint of the enjoyment scale, $t(92) = 9.41$, $p < .001$, $d = 1.95$, suggesting that subjects rated the Nina puzzles more enjoyable than not. Examination of the rank ordering of puzzles indicated that 50% of the subjects rated the Nina puzzles most enjoyable of the three. This observed frequency was significantly higher than the chance expectation of 33.33%, $\chi^2(1) = 10.88$, $p < .002$, $\phi = .34$, offering additional evidence for the high level of initial enjoyment of the Nina puzzles.

Manipulation Checks

The effectiveness of the positive feedback manipulation was examined in two Treatment × Sex (6 × 2) analyses of covariance[3] covarying pretest enjoyment on the perceived performance item ("How well do you think you did on these puzzles?") from the Nina puzzle questionnaire for the experimental session and posttest. A planned contrast tested whether subjects in the four conditions receiving positive feedback (NRPF, TCRPF, PCRNNPF, and PCRNSPF) were higher in perceived performance than subjects in the two no-feedback conditions (NRNF, TCRNF). In this contrast the first four groups were assigned weights of +1 and the latter two groups were given weights of −2. Subjects who received positive feedback showed higher levels of perceived performance both immediately following the experimental session, $F(1, 86) = 7.08$, $p < .01$, $\eta = .28$, and at the posttest 1 month later, $F(1, 80) = 7.03$, $p < .01$, $\eta = .28$.

A Treatment × Sex (6 × 2) analysis of variance was performed on the seven postmanipulation scales. No significant effects were found for alert, comfortable, relaxed, motivated, excited, anticipated puzzle difficulty, or expected performance level, suggesting that there were no treatment differences in motivation as measured by these scales after the students heard the instruction tape but before they actually did the puzzles.

In order to examine possible differences between the two groups that received performance-contingent rewards, post hoc protected t tests were used to compare the PCRNSPF and PCRNNPF groups on the seven postmanipulation scales and on experimental and posttest perceived performance. PCRNSPF subjects were

---

[2] Six subjects graduated from high school before the administration of the posttest, so posttest enjoyment scores were not obtained for them.

[3] Sex of subject was included as a factor in all analyses of variance, although it was not relevant to the main hypotheses of this study. A significant sex effect for posttest perceived performance was found, $F(1, 74) = 4.33$, $p < .05$, $\eta = .24$, indicating that males thought they had performed better than females. A significant sex effect for expected performance indicated that males thought they would do better than females on the puzzles, $F(1, 80) = 6.78$, $p < .05$, $\eta = .27$. A significant main effect for sex on recall, $F(1, 80) = 6.62$, $p < .05$, $\eta = .28$, showed that males were higher in amount of incidental recall than females, suggesting that the females may have been more task oriented. The sex differences found in this study were unanticipated, and interpretation of them would require replication.

significantly higher than PCRNNPF subjects on expected performance level ("How well do you think you will do on these puzzles?"), alert, and posttest perceived performance (PCRNSPF Ms = 5.13, 4.93, and 5.84 vs. PCRNNPF Ms = 4.16, 3.69, and 4.72 on 7-point scales), ts(87) = 2.36, 2.46, and 2.32, respectively, all ps < .05. The two groups did not differ significantly on comfortable, relaxed, motivated, excited, anticipated puzzle difficulty, or experimental perceived performance. This pattern of significant differences suggests that the groups differed primarily in expectations for and perceptions of performance level.

Intercorrelation of the Dependent Measures

Table 2 presents the correlation matrix for the six measures of intrinsic motivation (pretest, experimental, and posttest enjoyment, time, volunteering, and extra puzzles), performance, recall, and experimental and posttest perceived performance. The average intercorrelation of the six measures was .51 (p < .001), and each individual correlation was significant at the p < .001 level, indicating that all of the operationalizations of intrinsic motivation were positively interrelated.

Performance was positively related to pretest and experimental enjoyment, $r(91)$ = .20 and .22; p < .05, but was not significantly related to any other measures of intrinsic motivation. Performance (actual) did correlate positively with experimental perceived performance, $r(91)$ = .33, p < .001. Recall did not correlate significantly with any measures of intrinsic motivation or performance.

Because the four intrinsic motivation variables measured during the experimental session were positively related, a principal-components factor analysis was performed on them in order to create one measure of motivation for the experimental session. Volunteering, extra puzzles, time, and experimental enjoyment had loadings of .57, .75, .60, and .73, respectively, on the first factor extracted, and standardized factor scores were computed for the resulting intrinsic motivation measure, which was used as the primary dependent variable in the main analyses.

Effects of Reward and Feedback on Intrinsic Motivation

A Treatment × Sex (6 × 2) analysis of covariance with pretest enjoyment as a covariate was performed on intrinsic motivation

Table 2
Intercorrelations of Dependent Measures

Measure	1	2	3	4	5	6	7	8	9
1. Pretest enjoyment									
2. Experimental enjoyment	.69***								
3. Posttest enjoyment	.55***	.69***							
4. Time	.33***	.44***	.42***						
5. Volunteering	.37***	.50***	.40***	.33***

Table 3
Reward Condition Means for the Dependent Variables

Measure	Reward condition/contrast weight					
	NRPF/ +3	NRNF/ +1	TCRPF/ +1	TCRNF/ −1	PCRNSPF/ −1	PCRNNPF/ −3
Intrinsic motivation	1.05	−.16	.39	−.64	.07	−.96
Posttest enjoyment	38.47	33.09	35.36	31.96	35.97	29.96
Recall	2.56	2.44	3.13	2.30	1.49	1.22
Performance	8.87	7.81	8.56	8.27	9.00	8.62

Note. For the intrinsic motivation measure, standardized factor scores were created from volunteering, extra puzzles, time, and experimental enjoyment variables. NRPF = no reward – positive feedback. NRNF = no reward – no feedback. TCRPF = task-contingent reward – positive feedback. TCRNF = task-contingent reward – no feedback. PCRNSPF = performance-contingent reward (norms supplied) – positive feedback. PCRNNPF = performance-contingent reward (no norms) – positive feedback.

and posttest enjoyment. The effect of the pretest enjoyment covariate was highly significant for both intrinsic motivation, $F(1, 86) = 56.98$, $p < .001$, $\eta = .63$, and posttest enjoyment, $F(1, 80) = 39.99$, $p < .001$, $\eta = .58$, indicating that, as expected, intrinsic interest following the experimental manipulation was linearly related to initial task interest. No effects involving sex were significant for either dependent measure.

A planned contrast was used to test the main effect of treatment. Weights for the contrast were operationalized according to the control hypothesis as follows: no reward – no feedback—+1; no reward – positive feedback—+3; task-contingent reward – no feedback—−1; task-contingent reward – positive feedback—+1; performance-contingent reward (norms supplied) – postive feedback —−1; and performance-contingent reward (no norms) – positive feedback—−3. These equal interval weights are based on the assumption that the predicted effects are all equal in magnitude. This contrast tests the prediction that task-contingent rewards will produce negative effects relative to control conditions of no reward, that positive feedback will produce positive effects relative to conditions of no feedback, and that these two effects do not interact. This contrast also tests the prediction that performance-contingent rewards will decrease intrinsic motivation more than task-contingent ones and that performance-contingent rewards with no norms supplied will decrease intrinsic motivation more than performance-contingent rewards with norms supplied.

Means for the two dependent measures of intrinsic motivation are presented in Table 3. As predicted, the treatment planned contrast was highly significant for both measures: intrinsic motivation, $F(1, 86) = 12.72$, $p < .001$, $\eta = .36$, and posttest enjoyment, $F(1, 80) = 9.58$, $p < .005$, $\eta = .33$.[4] Thus intrinsic motivation was enhanced by positive feedback and undermined by rewards, particularly performance-contingent ones. This treatment planned contrast tests the overall patterning of the six cell means with respect to the predictions specified by the weights. Because this overall test incorporates several specific predictions, and since particular cell comparisons are relevant with respect to comparison with other studies, several additional nonorthogonal but theoretically relevant planned comparisons were computed for the primary dependent measure, intrinsic motivation.

In the four cells in which task-contingent reward or no reward was crossed with positive feedback or no feedback (TCRNF, TCRPF, NRNF, and NRPF), task-contingent rewards were found to reduce intrinsic motivation relative to control conditions of no reward, replicating the overjustification effect: TCRNF and

[4] This planned contrast was also significant for each of the four dependent measures combined to form the intrinsic motivation measure, in four separate analyses of variance on time, extra puzzles, volunteering, and experimental enjoyment.

TCRPF versus NRNF and NRPF, $t(87) = 1.78$, $p < .05$, one-tailed,[5] $d = .38$; and positive feedback increased interest relative to no feedback: NRPF and TCRPF versus NRNF and TCRNF, $t(87) = 2.74$, $p < .05$, $d = .59$. The interaction between task-contingent reward and feedback was not significant. Comparison of the two effect sizes (*d*s) suggests that the positive feedback effect was stronger than the overjustification effect.

Planned comparisons were also computed for the four cells with positive feedback (NRPF, TCRPF, PCRNSPF, and PCRNNPF), which represent the conceptual replication and extension of the Karniol and Ross (1977) design. The TCRPF and PCRNSPF means were not significantly different, but both were significantly lower than the control group: TCRPF and PCRNSPF versus NRPF, $t(87) = 2.01$, $p < .05$, $d = .43$. Thus the Karniol and Ross results were not replicated: Performance-contingent rewards, as well as task-contingent ones, reduced interest relative to control conditions. Furthermore, the Karniol and Ross prediction for the more informational PCRNNPF group was not supported; the PCRNNPF group was significantly lower than the PCRNSPF group in interest, $t(87) = 1.76$, $p < .05$, one-tailed, $d = .37$. Additionally, although the PCRNSPF group was not significantly lower than the TCRPF group, PCRNNPF rewards were significantly more undermining than TCRPF ones, $t(87) = 2.34$, $p < .05$, $d = .50$, and the two performance-contingent rewards considered together were significantly more undermining than the task-contingent one: PCRNNPF and PCRNSPF versus TCRPF, $t(87) = 1.67$, $p < .05$, one-tailed, $d = .36$, replicating the results of Deci (1972b).

Effects of Treatment on Performance and Recall

Treatment × Sex (6 × 2) analyses of covariance covarying pretest enjoyment were performed on incidental recall and performance. There were no significant effects for performance.

It was predicted that subjects offered performance-contingent rewards would be more task oriented and would recall fewer irrelevant details than subjects offered no rewards or task-contingent ones. A planned contrast comparing the two performance-contingent conditions (PCRNSPF and PCRNNPF: −2) with the other four conditions (NRNF, NRPF, TCRNF, and TCRPF: +1) was significant, $F(1, 86) = 8.95$, $p < .005$, $\eta = .32$, indicating that recall was lower in the two performance-contingent conditions, as predicted. The effect of the pretest enjoyment covariate was not significant ($F < 1$). Amount of recall, then, did not vary with the subjects' initial enjoyment of the puzzles. No other effects, except those involving sex, were significant for this measure.

Discussion

The control hypothesis received very strong support in this study. Performance-contingent rewards, particularly informational ones, were found to undermine subsequent intrinsic motivation more than task-contingent ones, which produced decrements in intrinsic motivation relative to control conditions of no reward. This pattern of results was found across five different operational definitions of intrinsic motivation, some of which were behavioral and some of which were self-report, attitudinal measures. Most striking, perhaps, is the fact that this pattern of results was still found 1 month after the experimental manipulation had taken place, on the task enjoyment measure.

The findings of this study lend support to the generalizability of the overjustification effect, which was replicated using a different subject population (high school students as opposed to college sophomores or preschoolers), a different experimental activity, and a different reward (notebook and pens, as opposed to the cash usually offered to adult subjects). The enhancing effect of positive feedback was also replicated, and this effect was found to be independent of the overjustification effect. This finding has important implications for the comparison of previous studies and for the identification of appropriate control groups.

---

[5] All reported *p* levels are two-tailed unless otherwise stated.

Since the receipt of a performance-contingent reward means that a subject has received both a reward *and* positive feedback concerning performance, the appropriate control group for examination of the effects of rewards may be a group that receives the same positive feedback but no reward. The comparison of performance-contingent and task-contingent rewards requires that the task-contingent group receive the same positive feedback, assuming that the feedback does not interact with the offer of a reward. On the other hand, it can be argued that the feedback inherent in a performance-contingent reward is an integral part of the reward itself, in which case it would not be unreasonable to compare performance-contingent rewards with task-contingent rewards or controls without positive feedback added. Choice of an appropriate comparison group is therefore somewhat arbitrary but of course affects the nature of the conclusions drawn.

Both kinds of performance-contingent rewards were found to reduce intrinsic motivation relative to control conditions of no reward. The informational reward (no norms) decreased intrinsic motivation more than the noninformational (norms supplied) reward, as predicted. Although the reward itself contained more information, subjects in both conditions received the same amount of information about their performance. In the noninformational condition, subjects knew how many Ninas they had to find and knew that they were doing well as soon as they found four Ninas. Subjects in the informational condition, on the other hand, had no idea about their performance level until after they finished the puzzles and received their reward. Intrinsic motivation may have been lower in the informational condition because the reward was more controlling (students had to perform as well as possible for the whole session, whereas those in the noninformational condition were less controlled because of the lesser demand of having to find four Ninas), or intrinsic motivation may have been higher in the noninformational condition because of the greater amount of feedback available to subjects during the actual process of doing the puzzles. Positive feedback may be more effective if it is supplied (or implied by preestablished norms) during the process of task involvement (so that subjects feel that they are doing well) rather than after task completion.

The informational hypothesis of Karniol and Ross (1977) received no support in this study. The means for intrinsic motivation fell in almost the exact opposite ordering of the pattern predicted by their hypothesis. It was originally predicted that their hypothesis would not be supported in this study because of differences in subject populations, but post-experimental conversations with students revealed that the nature of the experimental activity might be an important determinant of the relative salience of controlling versus informational aspects of performance-contingent rewards. Although students enjoyed doing the Nina puzzles, their enjoyment did not seem related to competence concerns. Enjoyment of the task was only slightly related to actual performance level, $r(91) = .22$, $p < .05$. Neither performance nor perceived performance was significantly related to any of the other measures of intrinsic motivation, suggesting that actual or perceived competence is not always an integral part of intrinsic motivation.

Intrinsically motivated activities may be engaged in for their own sake (e.g., drawing with magic markers and reading novels) or for the feelings of competence they produce (e.g., games, puzzles, and sports). This is, of course, an unrealistic dichotomy, because most activities involve both kinds of intrinsic satisfaction, but the extent to which an activity is relatively more competence relevant or fun relevant may determine whether informational or controlling aspects of a performance-contingent reward will be more salient to an individual.

The results of the analyses of recall differences are particularly interesting. The fact that recall was unrelated to the measures of intrinsic motivation and unrelated to performance, yet was affected by reward condition, suggests that this measure tapped an important dimension of task involvement that has not previously been examined in overjustification studies. The finding that contingently rewarded subjects did not remember

as much about the puzzles as did other subjects, but did not find any more Ninas either, suggests that they may have been using a more answer-oriented strategy that did not prove to be effective in terms of performance on these particular puzzles. Exactly what sort of processing strategy is gauged by the recall measure employed in this study is not clear, but the results of the analyses lend support to Condry's (1977) contention that more attention needs to be directed toward an exploration and understanding of the process of task involvement.

Variables That Moderate the Attitude–Behavior Relation: Results of a Longitudinal Survey

Andrew R. Davidson
University of Washington

James J. Jaccard
Purdue University

The following factors were hypothesized to moderate the attitude–behavior relation: (a) the behavioral sequence that must be successfully completed prior to the occurrence of the behavior, (b) the time interval between the measurement of attitudes and behavior, (c) attitude change, (d) the respondent's educational level, and (e) the degree of correspondence between attitudinal and behavioral variables. The behaviors investigated were having a child and using oral contraceptives. A stratified random sample of 244 married women in a midwestern urban area was studied during a three-wave, 2-year longitudinal study. Selection of attitudinal and belief measures was guided by the Fishbein model of behavioral intentions. Consistent with the hypotheses, the relations between behavior and both intention and the model's attitudinal and normative components were substantially attenuated by (a) events in the behavioral sequence not under the volitional control of the actor, (b) an increase in the time interval between the measurement of attitudes and behavior from 1 to 2 years, and (c) changes in the model's attitudinal and normative components during the first year. The respondent's educational level did not affect attitude–behavior consistency. Finally, the attitude–behavior correlation increased significantly as the degree of correspondence between the two variables increased.

Wicker (1969) concluded his comprehensive review of the attitude–behavior relation with the suggestion, "It is considerably more likely that attitudes will be unrelated or only slightly related to overt behaviors than that attitudes will be closely related to actions" (p. 76). Rather than signaling a decrease in research on this topic, pessimistic reviews by Wicker and others (e.g., Deutscher, 1966, 1969; Ehrlich, 1969; McGuire, 1969) appear to have prompted a renewal of interest in the relationship between attitude and action. One encouraging line of inquiry has focused on methodological refinements in the attitudinal and behavioral measures. By assessing both variables at corresponding levels of specificity, that is, measuring attitude toward the act for the prediction of a specific behavior or measuring a global attitude toward an object for the prediction of a multiple-act behavioral criterion, a reasonable degree of predictive accuracy can be obtained (Ajzen & Fishbein, 1973, 1977; Fishbein & Ajzen, 1974; Heberlein & Black, 1976; Weigel & Newman, 1976; Weigel, Vernon, & Tognacci, 1974; Weinstein, 1972; Wicker & Pomazal, 1971).

A second line of inquiry, encouraged by Kelman (1974), has attempted to specify the personal and situational variables influencing the extent to which people act in accord with their stated attitudes and beliefs. Individual difference variables that have been found to moderate attitude–behavior correspondence include the degree of affective-cognitive consistency (Norman, 1975), the tendency to ascribe responsibility to the self (Schwartz, 1973), and the degree of self-monitoring

This research was supported by Research Grant HD 07024-01,02,03 from the National Institute of Child Health and Human Development. We are grateful to Marilyn Cohen for her substantial aid both in supervising the interviewers and data coders and in locating respondents who moved.

(Snyder & Tanke, 1976). Similarly, a number of situational variables appear to moderate the attitude–behavior relation. For example, Warner and DeFleur (1969) found that the public versus private nature of the behavior interacts with attitude in influencing attitude–behavior consistency, and Snyder and Swann (1976) demonstrated that situations that increase the relevance of salient attitudes as guides to actions increase the correspondence between attitude and action. A recent series of studies (Fazio & Zanna, 1978; Fazio, Zanna, & Cooper, 1978; Regan & Fazio, 1977) provide support for the notion that attitudes formed through direct behavioral experience with the attitude object are more predictive of later behavior toward that object than are attitudes based upon indirect, nonbehavioral experience. In summary, several personal and situational factors have been found to affect the attitude–behavior relation. As Regan and Fazio (1977) commented, "The question facing researchers is, therefore, no longer *whether* an individual's attitudes can be used to predict his overt behavior, but *when*" (p. 30, italics in the original).

The present research continues the study of factors that moderate the degree of attitude–behavior consistency and investigates the following variables:

1. Sequence of prior events. As Fishbein and Jaccard (1973) have observed, the occurrence of a behavior under investigation is frequently dependent upon the successful completion of a sequence of prior events. For example, in order to have a child a woman must (a) have intercourse, (b) not use birth control, (c) conceive, and (d) not have a spontaneous or induced abortion. While some of the sequences are potentially under the control of the actor (e.g., not using birth control), others are not (e.g., conception). If performance of the final behavior requires the successful completion of sequences not under the volitional control of the actor, it is hypothesized that attitude toward the behavior will provide a better estimate of the likelihood that the actor will initiate the sequence than that the actor will complete the sequence and perform the behavior in question.

2. Attitude change. In a recent review of the attitude–behavior literature, Schuman and Johnson (1976) noted that little attention has been paid to the possibility that attitude change may occur between the measurement of attitude and behavior. They commented, "The extent to which A–B correlations are reduced because of real changes in underlying attitude needs to be identified as far as possible" (p. 178). Such identification is impossible in most studies because attitude is assessed at only one time. In the present research, attitude was measured twice prior to the performance of behavior in order to detect attenuation attributable to attitude change. Respondents whose attitudes remain stable are hypothesized to exhibit greater attitude–behavior consistency than respondents who experience attitude change.

3. Time interval. A third variable hypothesized to influence the degree of relation between attitude and behavior is the time interval between the measurement of attitude and the performance of behavior. As Fishbein and Jaccard (1973) noted, it is probably the processes occurring during that time interval —most notably exposure to new information —and not the passage of time per se that moderate the relation. This hypothesis is conceptually similar to the one above; the longer the time interval between the measurement of attitude and behavior, the higher the probability of exposure to new information and, in turn, attitude change.

Three previous investigations have reported data relevant to the influence of temporal instability on attitude–behavior consistency. Norman (1975) regressed behavior (volunteering to be a subject) on attitudes toward acting as a subject, assessed both 3 and 6 weeks prior to the measurement of behavior. For each of three attitudinal measures, the second administration was more highly correlated with behavior than the first, but the differences were not statistically significant. It has been suggested (Schwartz, 1978) that for this behavior the 3-week interval between attitude assessments was too brief for an unambiguous effect to be detected. In studies of voting behavior, Kelley and Mirer (1974)

have reported that for some subgroups the time interval between the measurement of voting behavior and attitudes can moderate the attitude–behavior correlation. Analyses of data from the 28% of the subjects judged most likely to change their minds found that a substantial proportion of variance in errors of prediction was accounted for by the number of days that intervened between the interview and the election. In the final and most recent investigation, Schwartz (1978) regressed stated willingness to tutor blind children on perceived moral obligation to tutor blind children, measured both 3 and 6 months prior to the criterion measure. The correlation with the criterion was significantly higher over the shorter time interval. However, as Schwartz noted, it is uncertain whether the results obtained with perceived moral obligation can be generalized to more traditional attitude scales measuring evaluation. In sum, although specific aspects of each of these studies—interval between attitude assessments, nature of the subsample investigated, nature of the predictive variable—have precluded a clear demonstration of the influence of time interval on the consistency between behavior and the evaluation of the behavior, these studies together provide a sound basis for positing the present hypothesis.

4. Respondent's education. Consistent with formulations proposed by Peak (1955), Rosenberg (1956), and Fishbein (1963), attitude toward a behavior is viewed as the sum of one's beliefs about the consequences of performing the behavior multiplied by the evaluation of those consequences. Such formulations, with their emphasis on cognitive-affective consistency, are frequently criticized as having greater validity for college students and intellectuals than for the majority of the population (cf. Bem, 1970). If such critiques are correct, education should interact with attitudes in the prediction of behavior, and degree of attitude–behavior consistency should correlate positively with the respondent's educational level. The findings of Rokeach (1973) also lead to the hypothesis that greater consistency will be observed for respondents with more education. In a national sample of American adults, the instrumental value *logical* defined as *consistent, rational* was more positively valued by highly educated respondents than by those with less education.

5. Correspondence between attitudinal and behavioral variables. As noted earlier, if attitude and behavior are both measured at a similar level of specificity, a reasonable relation is generally observed. In an extension of the specificity hypothesis, Ajzen and Fishbein (1977) maintain that attitudinal and behavioral variables are defined by four elements: an *action*, the *target* the action is directed toward, the *context* in which the action is to be performed, and the *time* at which the action occurs. They argue that the correlation between attitude and behavior is determined in part by the degree of correspondence or match between the elements comprising the two variables. They classified past studies in terms of the correspondence between attitude and behavior on two of the four elements, target and action. Consistently significant attitude–behavior correlations were obtained only if there was high correspondence between target and action elements. Their investigation, however, examined the moderating effects of target and action correspondence by comparing attitude–behavior correlations obtained from different studies. In the present research, the effects of target, action and, in addition, time correspondence on attitude–behavior consistency are tested within one study. It is hypothesized that as the degree of correspondence increases, the obtained attitude–behavior correlation will increase.

Attitude Model

The selection of attitudinal measures was guided by the Fishbein (1967) model of behavioral intention. The model is predicated on the assumption that most human behavior of concern to social scientists is to some degree volitional in nature and hence guided by the behavioral intent of the individual. Algebraically, the model is expressed as follows:

$$B \sim BI = [\sum_{i=1}^{n} B_i E_i] W_1 + [\sum_{i=1}^{m} NB_i MC_i] W_2, \quad (1)$$

where B = overt behavior, BI = the behavioral intention to perform the behavior, B_i = the belief (perceived probability) that performing the behavior will lead to consequence X_i, E_i = the evaluation of X_i, NB_i = the perceived expectation of Referent i, MC_i = the motivation to comply with Referent i, n = the number of salient consequences, m = the number of salient normative beliefs, and W_1 and W_2 = empirically determined regression weights.

As Peak (1955), Rosenberg (1956), and Fishbein (1963) have theorized, the ΣB_iE_i component is viewed as an index of the person's attitude toward performing the behavior (*Aact*). Fishbein and Ajzen (1975) maintain that the second predictive component (ΣNB_i-MC_i) assesses the influence of the social environment or the general subjective norm (*SN*) on behavior. Empirical support for the equivalence of ΣB_iE_i and *Aact* and of ΣNB_i-MC_i and *SN* is discussed in Fishbein and Ajzen (1975).

According to the model, any variable other than the attitudinal and normative components can influence *BI* only indirectly. Social, demographic, and personality characteristics of the respondent can affect intentions only if they influence ΣB_iE_i or ΣNB_iMC_i or their relative weights. Thus if this framework is correct, such variables as education should not have a direct effect on the magnitude of the relation between the components of the model and intention, and hence behavior.

Fishbein and Ajzen (1975) argue that the relation between *BI* and *B* should be very strong, provided that intention and behavior are measured at correspondent levels of specificity and that nothing intervenes to alter intention. Whenever a strong intention–behavior relation is observed, the behavior in question should also be predictable from the attitudinal and normative components. Assuming a significant *BI–B* correlation, it is hypothesized that behavior can be predicted from a linear combination of the attitudinal and normative components. In addition, it is hypothesized that the variables moderating the intention–behavior relation will also moderate the relation between attitudes, subjective norms, and behavior.

Behavioral Domain

The behaviors chosen for study were childbearing and contraceptive use. While social scientists have met with success in documenting fertility differentials on the basis of social and demographic variables, (cf. Rindfuss & Sweet, 1977) there has been a marked lack of success in explaining fertility behavior with psychological constructs. Two major fertility surveys, the Indianapolis study (Whelpton & Kiser, 1946–1958) and the Princeton study (Westoff, Potter, Sagi, & Mishler, 1961) failed to find any noteworthy relationships between psychological variables (primarily personality measures) and fertility and family planning behaviors.

Recently, research findings have indicated that a few psychological models that can be categorized as expectancy models are of some utility in the prediction of fertility decision making (see, for example, Beach, Townes, Campbell, & Keating, 1976; Davidson & Jaccard, 1975; Werner, Middlestadt-Carter, & Crawford, 1975). Working with the Fishbein model, Davidson and Jaccard (1975) investigated attitudes concerning three family planning behaviors in a sample of married women. In support of the model, ΣB_iE_i and ΣNB_iMC_i explained an average of 60% of the variance in behavioral intentions.

The data reported in Davidson and Jaccard (1975) were obtained during the first wave of a three-wave longitudinal survey. The sample was reinterviewed both 1 year and 2 years after the initial interview. The present study examines the relation between intentions, at the first interview, of having a child during the next 2 years and using oral contraceptives during the next 2 years and the corresponding self-reports of behavior during the 2-year period.

Method

Sample

Respondents in the initial survey were 270 white married women, age 18–38 years, residing in a mid-

western urban area. The sample was stratified by three levels of socioeconomic status and two levels of religious affiliation (Catholic and Protestant). The sampling procedure was designed to select randomly 45 women for each cell of the 2×3 design. For a detailed description of the sampling strategy, see Davidson and Jaccard (1975).

Loss to Follow-Up

The respondents were reinterviewed both 1 and 2 years after the initial survey. Of the original 270 respondents, 244 completed all three interviews.[1] Approximately one half of the respondents lost to follow-up refused to be reinterviewed and the other half could not be located. Loss to follow-up did not significantly vary among the six cells of the sampling design.

Interviews

Approximately 1 hour was required for the respondent to complete each questionnaire. Although the interviews were self-administered, the interviewer remained in the house while the questionnaire was being completed to answer any questions the respondent might have. The respondent received $10 for each interview.

Measurement Procedures

To insure that relevant beliefs and referents for the attitudinal and normative components of the model were included in the precoded questionnaire, initial elicitation interviews were conducted with an independent sample of 55 women. These women were selected from the same population as the women in the longitudinal sample. The interviews identified four referents (e.g., husband, close friends) and nine beliefs (e.g., the effect of having a child on the husband–wife relationship, the woman's freedom to pursue other activities, the family budget, etc.) salient to the population. A list of the referents and beliefs included in the questionnaire is presented in Davidson and Jaccard (1976).

All predictive components were measured on 7-point adjective scales. Examples of the measures are

1. Behavioral intention (*BI*) (*I intend to have a child within the next 2 years*) was measured on a *likely–unlikely* scale.

2. Belief about the act (B_i) (*For me, having a child within the next two years would make my marriage stronger*) was measured on a *likely–unlikely* scale.

3. Evaluation of the consequence (E_i) (*Making my marriage stronger would be . . .*) was measured on a *good–bad* scale.

4. Attitude toward the act (*Aact*) (*For me, having a child within the next two years would be . . .*) was obtained by summing the responses to three evaluative scales: *good–bad, nice–awful, pleasant–unpleasant.*

5. Normative belief (NB_i) (*My parents think I should have a child within the next two years*) was measured on a *likely–unlikely* scale.

6. Motivation to comply (MC_i) was measured on a scale anchored by *generally speaking, I want to do what Referent* i *thinks I should do* and *generally speaking, I do not want to do what Referent* i *thinks I should do.*

7. General subjective norm (*SN*) (*People who are important to me and whose opinions I value think I should have a child within the next two years*) was measured on a *likely–unlikely* scale.

Scales assessing evaluations of consequences and attitude toward the act were scored −3 (bad) to +3 (good). All other scales were scored from 1 (unlikely; not motivated to comply) to 7 (likely; motivated to comply).[2] ΣB_iE_i and ΣNB_iMC_i were obtained by multiplying the score on each belief statement by the score on the corresponding evaluation or motivation to comply and then summing these products for all beliefs. In addition to the above items, the questionnaire assessed a number of fertility-related attitudes and contained measures of education, scored from 1 (sixth-grade education or less) to 8 (PhD or other professional degree), and other demographic variables.

A dichotomous criterion variable was created for each behavior. For childbearing, women reporting a birth between the first and third interviews were assigned a score of 1, and the remainder of respondents were assigned a score of 0. In families reporting a birth, the child was typically observed by the interviewer. For oral contraceptive use, women reporting that they used oral contraceptives at any time during the 2-year interval were scored 1, and women never using the pill were scored 0.

The ΣB_iE_i and ΣNB_iMC_i measures were obtained for only one of the behaviors—having a child. Due to time constraints, only the direct measures of the attitudinal and normative components, *Aact* and *SN*, respectively, were obtained for the second behavior—using oral contraceptives. In the first of the three

---

[1] Due to missing data and failure to follow instructions, the sample sizes in the following analyses range from 242 to 244.

[2] In our previous studies all scales were scored −3 to +3. However, we now recognize that with the exception of the evaluation measures, the remainder of scales are assessing variables that are theoretically unipolar (e.g., subjective probability). Hence, the unipolar scales are scored 1 to 7 in the present analysis. A comparison of variables formed from both the present and previous scoring rules indicated that the two were substantially intercorrelated; for ΣB_iE_i, $r = .93$, and for ΣNB_iMC_i, $r = .76$. For a discussion of unipolar versus bipolar scoring of attitude and belief measures, see Fishbein and Ajzen (1975, pp. 82–86).

interviews, questions referred to performing each behavior during the next 2 years. In the second interview, the questionnaire was adjusted to query the respondents about having a child and using oral contraceptives during the next year.

Results

The first half of this section focuses on intention–behavior consistency and the factors hypothesized to influence the degree of consistency. The second half investigates the prediction of behavior from the model's attitudinal and normative components and examines the variables that moderate that relation.

Prediction of Behavior from Behavioral Intention

The intention–behavior relation. For each behavior a point-biserial correlation was computed between behavioral intention, measured during the initial interview, and behavior during the 2-year period. The *BI–B* correlation was .526 ($p < .01$) for childbearing and .678 ($p < .01$) for contraceptive use. The relative magnitude of these two correlations is probably influenced by the extent to which each behavior is under volitional control. While contraceptive use–nonuse is to a large degree under the control of the actor, childbearing is determined by an interaction of biological and volitional events.

The sequence of prior events. As discussed above, in order to bear a child a woman must have intercourse without using contraception, conceive, and not have a spontaneous or induced abortion. It was hypothesized that intention would provide a better estimate of the probability that the person would initiate the sequence than of the likelihood that the person would complete the sequence and perform the behavior in question (bear a child). Women were classified as initiating the sequence if, in the final survey, they responded that by having intercourse while not using contraception they had been attempting for at least 9 months to become pregnant or if they actually gave birth during the 2-year period. The point-biserial correlation of intention with birth or attempted conception was .615 ($p < .01$). As hypothesized, this correlation was significantly larger than the correlation of intention with birth, .615 versus .526, $t(241) = 4.45$, $p < .01$.

The time interval between the assessment of intention and behavior. It was hypothesized that as the time interval between the measurement of intention and behavior increases, the *BI–B* correlation decreases. This hypothesis was tested by comparing the *BI–B* correlation for the 2-year period (Year 1 to Year 3) with the correlation for the 1-year period (Year 2 to Year 3). In support of the hypothesis, for both behaviors, the correlation for the 1-year period was significantly higher than for the 2-year period (oral contraceptive use: .853 versus .678, $z = 5.21$, $p < .01$; birth or attempted conception: .829 vs. .615, $z = 4.95$, $p < .01$).[3]

Change in intention. The effect of time interval on intention–behavior consistency can be attributed to processes occurring during the time interval (e.g., exposure to new information and attitude change). To demonstrate directly the effect of change on the *BI–B* correlation it was necessary to identify respondents who changed intentions between the first two waves of the three-wave survey. However, as Kiesler (1977) has shown, a respondent might change her intention to make it consistent with her behavior during the prior year. For example, if a woman did not intend to have a child at the first interview but became pregnant during the first year of the study, she would probably indicate an intention to have a child at the second interview. Such a case would more accurately be classified as a missed prediction rather than as a change in intention. Hence, only respondents not performing the behavior (becoming pregnant, bearing a child, using oral contracep-

[3] As these correlations are themselves intercorrelated, it is incorrect to use the traditional Fisher's z transformation (Hayes, 1963, pp. 529–532) to test for the significance of differences between them. Rather, the correlations were appropriately compared using a test initially suggested by Pearson and Filon and reported in Peters and Van Voorhis (1940, p. 185).

tives) during the first year were eligible for the classification of change in intention.

Eligible respondents were classified into one of three groups based on their responses at the first and second interviews to the relevant intention items. They were classified as intenders if they indicated it was slightly, moderately, or very likely that they would perform the behavior. Respondents indicating that performance of the behavior was slightly, moderately, or very unlikely were classified as nonintenders. Women checking the midpoint of the scale (neither likely nor unlikely) were classified as uncertain. Any eligible respondent who changed classification from Time 1 to Time 2 was identified as having changed her intention.

Based on this procedure, 30 women were identified as having changed their childbearing intentions, and the remaining 214 women were classified as nonchangers. For oral contraceptive intentions, 36 women were classified as changers and 206 as nonchangers. Each *BI–B* correlation was then computed separately for the change and nonchange respondents. For both childbearing and contraceptive use, the intention–behavior correlation was substantially lower for women who changed intentions than for nonchangers (birth or attempted conception: $-.015$ vs. .742, $z = 4.65$, $p < .01$; oral contraceptive use: $-.397$ vs. .880, $z = 9.57$, $p < .01$). Thus, in support of the hypothesis, change in intention attenuated the intention–behavior relation over the 2-year period.

Respondent's educational level. It was hypothesized that the respondent's educational level would be positively related to the degree of intention–behavior consistency. Hence intention should interact with education in the prediction of behavior. To test this hypothesis, behavior was regressed hierarchically (Allison, 1977; Cohen, 1978) against intention, education and the multiplicative interaction term of Intention × Education. For neither behavior did the inclusion of the interaction term lead to a significant increment in R^2; both Fs < 1. Therefore the hypothesis that educational level moderates the intention–behavior relation was not supported.

In summary, there was a reasonably strong correlation between intentions and behavior during the subsequent 2 years. Consistent with the hypotheses, however, this relation was attenuated by (a) events in the behavioral sequence not under the volitional control of the actor, (b) changes in intention, and (c) the time interval between the assessment of intention and behavior. The respondent's education level did not moderate the intention–behavior relation.

A demonstrated relation between what people say they are going to do (intention) and what they actually do (behavior) is probably of greater applied than theoretical significance. Once strong intention–behavior consistency has been observed, however, the relation between the attitudinal and normative components of the model and behavior is of considerable theoretical interest. The subsequent analyses examine this relation.

Prediction of Behavior From the Model's Attitudinal and Normative Components

The regression of behavior on attitudes and norms. For both contraceptive use and childbearing, the dichotomous index of behavior during the 2-year period was regressed on attitudes and norms, measured during the initial interview. As indicated in Rows 1 and 3 of Table 1, for each behavior both of the model's components received significant regression weights in the prediction of behavior. For the prediction of birth the multiple correlation was .508 ($p < .01$), and R^2 adjusted for shrinkage was .252. For the prediction of oral contraceptive use, the multiple correlation was .606 ($p < .01$) and R^2 adjusted for shrinkage was .362.

The sequence of prior events. It was hypothesized that events in the behavioral sequence not under the volitional control of the actor would attenuate the prediction of behavior from the model's components. The data presented in row 2 of Table 1 support this hypothesis. The multiple correlation with birth or attempted conception is significantly higher than the correlation with birth, .595 versus .508; $t(241) = 4.33$, $p < .01$.

Table 1
Regression of Fertility and Contraceptive Behavior on Attitudes and Norms

Behavior	Standardized regression coefficients		R	R^2	R^2 adjusted for shrinkage
	$\sum B_iE_i$	$\sum NB_iMC_i$			
Birth[a,b]	.187	.361	.508	.258	.252
Birth or attempted conception[a,c]	.203	.438	.595	.354	.349
	Aact	*SN*			
Use of oral contraceptives[d,e]	.392	.268	.606	.367	.362

Note. All regression coefficients and multiple correlations are significant ($p < .01$). Abbreviations are as follows: $\sum B_iE_i$ = one's beliefs about the consequences of performing the behavior multiplied by the evaluation of those consequences; $\sum NB_iMC_i$ = one's normative beliefs about performing the behavior multiplied by one's motivation to comply with those perceived norms; *Aact* = one's attitude toward performing the behavior; *SN* = one's subjective norm (generalized normative belief) about performing the behavior.
[a] $N = 244$.
[b] Coded: birth during the 2-year period = 1; no birth = 0.
[c] Coded: birth or attempted conception during the 2-year period = 1; no birth or attempted conception = 0.
[d] $N = 242$.
[e] Coded: use of oral contraceptives during the 2-year period = 1; nonuse = 0.

Time interval between the assessment of the model's predictive components and behavior. For both behaviors, the multiple correlation with the model's predictive components was higher for the 1-year period (Year 2 to Year 3) than for the 2-year period (Year 1 to Year 3). However, for birth or attempted conception the difference between the *R*s failed to achieve the traditional significance level (oral contraceptive use: .704 vs. .606, $z = 2.48$, $p < .01$; birth or attempted conception: .649 vs. .595, $z = 1.39$, $p < .09$).

Attitudinal and normative change. As previously noted, the effect of time interval on attitude–behavior consistency is attributable, in part, to attitude and belief change occurring during the interval. To demonstrate the effect of change on the correlation between behavior and the model's components, it was necessary to identify respondents whose attitudes or norms changed from Interview 1 to Interview 2. The procedure used here is similar to the one described above for assessing change in *BI*. First, to differentiate norm and attitude change from post hoc justification of prior behavior, only respondents not performing the behavior (becoming pregnant, bearing a child, using oral contraceptives) during the first year were eligible for the classification of change in attitudes or norms. Next, separately for each behavior and each of the model's two predictive components, eligible respondents who changed from Time 1 to Time 2 were identified as changers, and the remaining respondents were classified as nonchangers. The correlation between the relevant component and behavior was then computed separately in each group. Consistent with the hypothesis, lower correlations were expected in the change than in the nonchange group.

Attitude toward the act of using oral contraceptives (*Aact*) was assessed by summing the responses to three evaluative scales, each scored +3 to −3. A score of 0 was categorized as a neutral attitude, a score greater than 0 was a positive attitude, and less than 0 constituted a negative attitude. Sixty-three eligible respondents changed attitude categories between Interview 1 and Interview 2. As predicted, the *Aact–B* correlation was substantially higher in the nonchange than in the change group (.733 vs. −.238; $z = 7.88$, $p < .01$).

Responses to the general subjective norm concerning the use of oral contraceptives

(*SN*) were also divided into three categories: uncertain (a score of 4, the midpoint of the scale), positive norm (a score greater than 4), and negative norm (a score less than 4). Seventy-four eligible respondents changed categories from Interview 1 to Interview 2. In support of the hypothesis, the *SN–B* correlation was significantly higher in the nonchange than in the change group (.682 vs. −.039; $z = 6.14$, $p < .01$).

For childbearing behavior, the midpoints of the scales for the $\Sigma B_i E_i$ and $\Sigma NB_i MC_i$ components had to be empirically identified. Using data from the first interview, the mean scores on $\Sigma B_i E_i$ and $\Sigma NB_i MC_i$ were determined separately for those intending and not intending to have a child. The score midway between the means was designated the neutral point on the scale. In the interval between Interview 1 and Interview 2, 34 eligible respondents moved across the neutral point of the $\Sigma B_i E_i$ measure, and 25 eligible respondents moved across the neutral point of the $\Sigma NB_i MC_i$ measure. Consistent with the prediction, the correlation of both $\Sigma B_i E_i$ and $\Sigma NB_i MC_i$ with birth or attempted conception was higher in the nonchange than in the change group ($\Sigma B_i E_i$: .580 vs. .011, $z = 3.38$, $p < .01$; $\Sigma NB_i MC_i$: .648 vs. −.061, $z = 3.71$).

Respondent's educational level. It was hypothesized that the respondent's educational level would interact with attitudes and norms in the prediction of behavior. To test this hypothesis, behavior was regressed hierarchically against the model's attitudinal and normative components, education, and the multiplicative interactions of Education × Each Component. For neither behavior did the inclusion of the interaction terms lead to a significant increment in R^2; both Fs < 1. Hence, the hypothesis was not supported.

In summary, there was a reasonably strong correlation between the model's attitudinal and normative components and behavior during the subsequent 2 years. Similar to the results obtained with behavioral intention, the prediction of behavior from attitudes and norms was attenuated by (a) events in the behavioral sequence not under the volitional control of the actor, (b) the time interval between the measurement of the model's predictive components and behavior (for childbearing there was only a trend in the hypothesized direction), and (c) changes in attitudes and norms. The respondent's educational level did not moderate the strength of the relation.

Table 2
Correlations Between Selected Attitudinal Variables and Behavior

Attitudinal variable	*r*
Use of birth control pills during the 2-year period[a]	
Attitude toward birth control	.083
Attitude toward birth control pills	.323*
Attitude toward using birth control pills	.525*
Attitude toward using birth control pills during the next 2 years	.572*
Birth or attempted conception during the 2-year period[b]	
Attitude toward children	−.007
Attitude toward having children	.187*
Attitude toward having a child in the next 2 years	.535*

[a] $N = 244$.
[b] $N = 242$.
* $p < .01$.

Correspondence Between Attitudinal and Behavioral Variables

It was hypothesized that the degree of correspondence between the elements of the attitudinal and behavioral variables would be positively related to attitude–behavior consistency. The present analysis investigated the effect of three elements on the attitude–behavior correlation: *action*, the *target* the action is directed toward, and the *time* at which the action occurs. As indicated in Table 2, four attitudinal variables, measured during the first interview, were correlated with the dichotomous behavioral measure of birth control pill use during the 2-year period. The attitudinal measures systematically varied with regard to the number of elements they had in correspondence with the behavioral measure, as follows: zero elements in correspondence (attitude toward birth control, $r = .083$, *ns*); one element in correspondence—target (attitude toward birth control pills, $r = .323$, $p < .01$); two elements in correspondence—target

and action—(attitude toward using birth control pills, $r = .525$, $p < .01$); three elements in correspondence—target, action, and time—(attitude toward using birth control pills during the next 2 years, $r = .572$, $p < .01$). In support of the hypothesis, for each successive increase in correspondence between attitude and behavior variables there was a significant increase (ranging from $p < .01$ to $p < .06$) in the magnitude of the attitude–behavior correlation.

Following a similar pattern, the dichotomous behavioral measure of birth or attempted conception during the 2-year period correlated −.007 (*ns*) with attitude toward children, .187 ($p < .01$) with attitude toward having children, and .535 ($p < .01$) with attitude toward having a child in the next 2 years. For each successive increase in correspondence there was a significant increase (all ps $< .01$) in the attitude–behavior correlation.

Discussion

The primary purpose of the present research was to investigate five factors hypothesized to influence the extent to which people act in accord with their stated attitudes. The investigation of the first of these factors, the sequence of prior events, directed attention to the behavioral variable. The majority of previous attitude–behavior research has focused exclusively on problems associated with attitudinal variables during attempts to account for low attitude–behavior correlations. However, the performance of a behavior is often dependent upon the successful completion of a series of behavioral events. As the present research has demonstrated, if all of these steps are not under the volitional control of the actor, intention will provide a better estimate of the probability that the actor will initiate the sequence than of the likelihood that the actor will complete the sequence and perform the behavior in question. These results suggest that future studies of attitude–behavior consistency should seek to identify and quantify the behavioral sequences that must be completed prior to the performance of the behavior of interest. Analyses can then isolate the sequences at which serious disruptions occur between attitudes and actions. From an applied perspective, such knowledge would be of considerable use in the selection of behavior-change strategies. This approach would lead to the identification of situations in which the most appropriate strategy is *not* to change attitudes but rather to institute policy changes making it easier for people to act in accord with their existing attitudes.

The second and third factors, attitude change and the time interval between the measurement of attitude and behavior, focused on instability in the attitude and belief variables. As the time interval decreased from 2 years to 1 year, there was a 58.3% increase in the amount of variance in oral contraceptive use accounted for by *BI*. The corresponding increase for childbearing was 81.7%. Substantial improvements in the prediction of behavior were also achieved when analyses were limited to the sample of respondents who did not exhibit attitude change. The magnitude of these effects directs attention to the problem of using static models in the analysis of a dynamic process. When stating attitudes and intentions about future behaviors, a respondent is probably assuming either that the environment will not change or that it will change in an anticipated manner. Unexpected changes (e.g., loss of employment, exposure to new information) can lead to a change in attitude and, if such changes are not monitored, to an apparent lack of consistency between attitudes and behavior. Future research should attempt to specify the personal and situational variables influencing attitudinal stability. From the studies reviewed above, some of the factors that might initially be hypothesized to contribute to stability include the extent to which the attitude was formed through direct behavioral experience with the attitude object (Fazio & Zanna, 1978; Regan & Fazio, 1977) and the individual difference variables of self-monitoring (Snyder & Tanke, 1976) and tendency to ascribe responsibility to the self (Schwartz, 1973).

The fourth factor hypothesized to moderate the attitude–behavior relation was the respondent's educational level. It was hypothesized that as completed years of schooling

increased, so would the magnitude of the attitude–behavior correlation. However, an interaction between education and attitude–behavior consistency was not observed. Hence, these results lend no support to the contention that consistency is especially prevalent among the highly educated. It appears unlikely that nonsupport for this hypothesis is attributable to lack of variance on the education variable; years of education ranged from 8 to 16. In addition, attitudinal models similar to the present one have provided good prediction of behavioral intentions and behavior in cross-cultural samples with considerably lower educational levels than the present sample (Davidson, Jaccard, Triandis, Morales, & Diaz-Guerrero, 1976; Davidson & Thomson, 1980). It should be noted that the present finding provides indirect support for the theoretical framework of Fishbein. As noted above, if the framework is correct, social, demographic, and personality characteristics of the respondent should not have a direct effect on the magnitude of the relation between the components of the model and intentions, and hence behavior.

The fifth factor hypothesized to moderate attitude–behavior consistency is the degree of correspondence between the elements of the attitudinal and behavioral variables. As the attitudinal measures moved along a continuum of correspondence in terms of the number of elements they had in agreement with the behavioral measure (from zero to three elements), their correlations with behavior significantly increased. The present results concerning the impact of action and target correspondence are consistent with the conclusions of Ajzen and Fishbein (1977). In addition, the findings highlight the impact of a third element, not previously investigated, the time during which the action occurs. To obtain reasonable predictions of behavior from attitudinal variables, it appears important to ensure correspondence in target, action, and time elements.

The findings from the present study also provide support for the predictive validity of the components of the model of Fishbein. Even prior to the adjustments made for attitude change and the sequence of events, both intention and the attitudinal and normative components measured at the first interview provided reasonable correlations with behavior during the subsequent 2 years (the lowest validity coefficient was .508).

A weakness in the present research is that the data on oral contraceptive use were obtained solely through self-reports. Hence it is not possible to determine if the respondents misrepresented their behavior in order to make it consistent with their previously stated attitudes and intentions. It appears doubtful that there was extensive misrepresentation, because the findings concerning oral contraceptive use were very similar to those for childbearing in terms of both the percentage of subjects correctly classified and the variables found to moderate the degree of attitude–behavior consistency. There was also a reliance on self-report data concerning the attempt to become pregnant. Respondents might have falsely indicated that they had been unsuccessfully trying for at least 9 months to become pregnant in an attempt to appear consistent with previously stated intentions. However, this rival hypothesis requires that the respondents admit something that is socially undesirable about themselves for the purpose of appearing consistent.

In conclusion, this research indicates that the contraceptive and fertility behavior of married women is quite predictable from behavioral intentions, attitudes, and normative beliefs. However, the degree of the relation is attenuated by events in the behavioral sequence not under the volitional control of the actor, the time interval between the measurement of behavior and the model's predictive components, changes in attitudes and beliefs, and the degree of correspondence between the attitudinal and behavioral variables.

Mind Over Matter: Perceived Success at Psychokinesis

Victor A. Benassi, Paul D. Sweeney, and Gregg E. Drevno
California State University, Long Beach

Four experiments showed that college students' estimates of success on a psychokinetic (PK) task were affected independent of actual performance. In Experiment 1, subjects given a positive introductory set or no set about PK evidenced more illusory control than subjects given a negative set. In Experiment 2, both degree of general belief in psychic phenomena and the number of practice trials that subjects received influenced performance estimates, with high believers who received 10 practice trials providing the highest estimates and low believers who received 1 practice trial the lowest. In Experiment 3, subjects actively involved with the PK task judged their performance more positively than passively involved subjects. Experiment 4 showed that when they were actively involved in the task, subjects with an internal locus of control gave higher estimates of their success than subjects with an external locus of control. When passively involved, internals and externals did not reliably differ in their estimates, but their estimates were lower than those of active/internals. These results support Langer's illusion-of-control theory and also highlight the importance of general psychic belief and locus-of-control orientation in affecting perceived success at a psychic task.

How do people come to believe in the existence of psychic phenomena? Although research on the determinants of psychic belief is sparse, we can presume that such beliefs are determined by a number of factors, including media inputs, impactful personal experiences, inherent biases in human reasoning, and so forth (Sweeney, Benassi, & Drevno, Note 1). The present studies focused on several factors affecting estimates of personal performance on a psychokinetic (PK) task. Our intention was to provide a partial answer to the question of how people come to believe in their personal efficacy. We suggest that the same variables affecting perceived control in general also influence judgments of perceived psychokinetic control.

Using Langer's (1975) illusion-of-control model, Ayeroff and Abelson (1976) reasoned that belief in success on a mental telepathy task could be influenced by the introduction of skill-related but irrelevant variables into the situation. They found that subjects permitted to choose the symbols to be transmitted in a standard mental telepathy task and/or to engage in a warm-up session thought they did much better on the task than subjects who were not provided with these experiences. Objectively, the subjects performed at chance levels.

Layton and Turnbull (1975) found that attitude toward and evaluation of ESP were systematically related to *performance* on an ESP task. Two experiments were conducted, and an ESP effect was found in the first study, but not in the second. In both studies the authors found that subjects with a positive attitude toward ESP and a positive evaluation of it *thought* they did better on the ESP task

We wish to thank Rhoda Lindner, David Dowell, Lyle Creamer, Barry Singer, Raphael Hanson, and Peggy Murray for their helpful comments. Thanks are extended also to Robert Root for his technical assistance.

Paul D. Sweeney is now at the University of Pittsburgh.

than their negative counterparts. In an early study, James and Rotter (1958) found that verbalized expectancies for success on an ESP task during extinction depended on whether subjects were told that ESP was a skill or chance task and whether they were given 100% or 50% reinforcement (positive feedback) during training.

In Experiment 1 we predicted that estimates of PK performance would vary with the instructional set. We hypothesized that subjects given a positive introductory statement about the existence of PK would rate their performance more positively than subjects given a negative set (cf. Layton & Turnbull, 1975). Additionally, we predicted that subjects given no specific set about PK would give higher estimates of success than those given a negative set, but subjects given no specific set would not differ in perceived success from positive-set subjects. This latter prediction derives from the finding that college students as a group are generally positive in their attitudes toward psychic phenomena (e.g., Jones, Russell, & Nickel, 1977; Polyella, Popp, & Hinsman, 1975). We hypothesized that our positive set merely provides support for what subjects already tend to believe.

Experiment 1: Instructional Set

Method

Subjects. Thirteen male and 24 female introductory psychology students met a course requirement at California State University, Long Beach, by participating in the study.

Apparatus. A device called a *die funnel*[1] was constructed in such a way that subjects could not see the outcome of their die tosses. A subject sat at one end of the funnel and tossed the die into the chute. The experimenter then opened a box at the opposite end, recorded the outcome, and returned the die to the subject.

Procedure. Individual subjects reported to the experimental room and were told that they were to be part of a study dealing with psychokinesis. Subjects were then randomly assigned to one of the following instructional set conditions:

1. (*Pro set*). Research studies have indicated that people have varying degrees of psychokinetic abilities, for example, they are able to bend spoons and repair watches without physically touching them. These abilities have been documented by scientists from both the USA and the USSR. The following study will attempt to verify and replicate these findings. Specifically, this study will concern itself with measuring the effect that one's psychokinetic abilities have on the throwing of dice.

2. (*Con set*). Much research has been done concerning people's psychokinetic abilities, that is, the alleged ability to move objects or alter their shapes without physically touching them, for example, bending spoons and repairing watches. The research demonstrates little or no evidence that people actually possess such abilities. The experiments by both United States and Soviet scientists that have tested these purported abilities have to date failed to establish evidence for PK. Our experiment is another in a long series in search of PK abilities.

3. (*Neutral set*). This will be an experiment investigating psychokinesis, that is, the ability to move objects or alter their shapes without physically touching them, for example, bending spoons or repairing watches.

After completing one of the above sets, Experimenter A left the room as Experimenter B entered. Blind to the set provided by Experimenter A, Experimenter B described the procedure for conducting the PK test as follows:

> We have constructed this apparatus called a *die funnel*. It acts as a funnel into which you will throw this die. The die will be put into this cup and then thrown into the funnel. It will tumble down to the end, whereupon I will record the outcome of the toss. As you will notice, the die has three sides painted green and three sides painted red [subject is shown the die]. For each of 20 trials we will run, you will choose a color and then I will ask you to concentrate your full mental energies for a period of 10 seconds on affecting the outcome of the toss. For example, you might choose the target color red; next you will concentrate for 10 seconds; then, when I say "begin," you will immediately toss the die into the funnel. I will then record the outcome of your toss on the sheet I am holding. Further, I should like you to indicate on this sheet [subject is given data sheet] whether you are confident or not confident that the color you chose actually comes up.

Upon hearing the above instructions, a subject completed 20 trials, after which he or she filled out a short questionnaire. In introducing the questionnaire, Experimenter B briefly described chance performance (i.e., about 10 hits) on the task the subject had just completed.

In this experiment and in the subsequent three experiments, subjects were debriefed through written feedback after all subjects had participated.

---

[1] Photographs of this apparatus may be obtained from the first author.

Table 1
Estimated Success as a Function of Instructional Set

Group	Number of confident trials (0–20)	Self-influence	Estimates on 20 more trials	Perceived correct
Pro (n = 13)				
M	11.85***	5.00	12.20**	11.90*
SD	2.79	2.90	2.19	2.39
Neutral (n = 10)				
M	12.60***	4.40	12.00**	11.50*
SD	1.27	1.43	2.40	1.51
Con (n = 14)				
M	7.57	3.36	9.80	9.90
SD	3.18	2.17	1.89	1.83

Note. For each dependent variable, a Fisher's least significant difference test was performed following the analysis of variance. None of the differences between the means of the pro- and neutral-set groups exceeded the critical values required at a p value of .05. However, for each measure, the p values adjacent to the means of the pro- and neutral-set groups indicate the level at which they are significantly different from the means of the con-set group.
* $p < .05$.
** $p < .025$.
*** $p < .001$.

Results

We found no evidence of sex differences on any of the measures taken in this study or in any of the subsequent three studies. Therefore all data have been collapsed across sex.

The mean success rate did not differ across groups ($F < 1$): pro = 11.6, neutral = 10.7, and con = 11.0. Binomial tests showed that no group performed significantly above or below chance levels. We also performed binomial tests to determine whether people deviated from chance performance on those trials on which they were confident of being correct, and we found the tests for each group to be clearly nonsignificant.[2]

Table 1 shows that there were significant differences on the confidence measure between the treatment groups, $F(2, 34) = 13.31$, $p < .001$, $\omega^2 = .280$. While the means for the pro- and neutral-set subjects did not systematically differ, both were significantly different from the mean for the con-set participants ($p < .001$ with Fisher's least significant difference [LSD] test).

Table 1 also shows the mean scores on the questions asked of subjects upon completion of the PK task. In response to the Likert format question "How much do you feel that your concentration influenced what colors came up? That is, how much PK influence do you feel you have exerted?" we found nonsignificant mean differences among groups, $F(2, 34) = 2.31$, $p > .05$. The results of this measure were in the same directional pattern as those on the other dependent measures. To the question "If you were given another 20 trials, on how many do you think you would influence what colors would come up?" we found a significant effect, $F(2, 34) = 5.04$, $p < .05$, $\omega^2 = .175$. We also found a significant difference on the question "On how many of the 20 trials do you think you correctly predicted what colors came up?":

[2] Combining the PK data from the three experimental groups resulted in a mean hit rate of 55.5%, which is nearly three binomial standard deviations from the expected mean of 50%. There are, of course, any number of factors that might have been responsible for this effect. The combined hit rate cannot account, however, for the significant estimated success differences among the experimental groups on the dependent measures. We may recall that the hit rates for groups did not separately deviate from chance. The combined group PK effect, while perhaps interesting, does not discount the result that belief measures were affected by the instructional set and not by actual performance.

$F(2, 34) = 4.06$, $p < .02$, $\omega^2 = .139$. Post hoc comparisons done on all of the significant analyses revealed that although the pro- and neutral- group means did not differ from each other, they were both significantly higher than the means for the con group ($ps < .05$ with Fisher's LSD test).

Discussion

The results support the notion that a variation in set can lead subjects to make differing estimates of performance on a PK task, independent of actual performance (cf. Layton & Turnbull, 1975). Subjects in the pro- and neutral-set conditions judged their performance to be more successful than subjects in the con-set condition. However, estimates of the pro and neutral groups did not reliably differ. Whether our manipulations actually influenced belief or only influenced verbal report remains an open question. A strong believer in psychic abilities, for example, may have been reluctant to tell the experimenter that she or he performed well when the experimenter had just stated that there is no evidence to support the existence of PK. In other words, the results could be an artifact of demand characteristics of the experimental situation. The results of the subsequent three experiments cannot easily be attributed to demand characteristics.

Subjects threw the die and chose the target color before each trial; the ratings of the neutral- and pro-set groups might have been lower if the experimenter had performed these functions. Additionally, the negative set seems to have overridden the effects of the subjects' active involvement with the task. Had these subjects been passively involved, we might expect their ratings to have been even lower than they were. Because involvement was not manipulated in this study, we cannot say to what extent active involvement influenced the judgments of our subjects separate from the effects of the instructional set. This orthogonal variation of set and involvement might clarify the contributions of these variables in determining perceived success.

Experiment 2: Practice and Belief

Based on the work of Langer (1975) we predicted that subjects given more prior exposure to a PK task would judge their performance during an actual test series more positively than subjects provided with less prior exposure. To the extent that skill-related variables are introduced into a chance situation, Langer found, people will judge their performance to be skillful. For example, practice in flipping a coin does not enhance subsequent performance, but the subject may mistakenly form the impression that it does. We also predicted that subjects with relatively strong general beliefs in psychic phenomena would give higher ratings of their performance on the PK task than more skeptical subjects would. Jones et al. (1977) found that subjects who scored higher on a paranormal belief scale gave higher estimates of their performance on a PK-type task than subjects who scored lower on the belief scale.

Method

Subjects. Fifty-five students, 30 female and 25 males, at California State University, Long Beach fulfilled an introductory psychology course requirement by participating.

Apparatus and materials. An apparatus called the die tumbler (see Footnote 1) allowed for electronic release of a die. The die, which sat on a platform, was released 10 seconds after a timer switch had been activated by the experimenter. During the experiment subjects sat at one end of the tumbler, from which they could see two lights: a red light that stayed on for the duration of the 10-second concentration period and a white light that signified the end of this period and the release of the die. The subjects could not see the outcome of the die tosses.

A portion of the Belief in the Paranormal Scale (BPS) was used to assess subject's general belief (see Table 1 of Jones et al., 1977, for the complete scale). The nine questions used were Numbers 1, 11, 15, 16, 19, 21, 23, 24, and 25.

Procedure. Same-sex subjects reported to the laboratory in groups of three or four. Subjects were given a definition of PK similar to the one in Experiment 1. They were then asked to inspect the die tumbler. The procedure was demonstrated, and subjects were asked to sit at predetermined spots located about 3 feet (1 m) from the tumbler. They sat at a desk separated by partitions, which prevented them from seeing each other's responses but allowed them to see the die tumbler. Subjects were

next told that when the red light on the die tumbler came on, they were to "concentrate your full mental energies on making the die land face up." The die used in Experiment 1 was then presented for all subjects to inspect.

According to procedure, the experimenter called out a target color and then started the 10-second concentration period. After the die was released, subjects completed the same confident/not confident checklist described in Experiment 1.

Subjects were assigned to a condition providing 1 or 10 practice trials in which they were given experience with the procedure to be used in the test series. After the practice trial(s), Experimenter A left the room, and Experimenter B entered and began the series of 20 trials. The sequence of target colors during practice and testing sessions was constant across conditions. Experimenter B was blind to the practice-trial condition of the subjects. Upon completion of the 20 trials, subjects filled out two Likert-format questionnaires. The first contained one question that asked, "How much do you feel that your concentration influenced what colors came up on the 20 trials?" The second questionnaire was the BPS.

Results

We found no evidence of PK influence. The mean hit rate was 9.2 for the group that performed 1 practice trial and 10.4 for the group that performed 10 practice trials ($t < 1$, *ns*). Also, as determined by binomial tests, neither group performed above or below chance. As in Experiment 1, subjects did no better or worse on the trials on which they were confident.

Within both trial groups a median split was done on the BPS questionnaire results. Subjects in the 1- and 10-trial conditions who scored above the median values of 32 and 31, respectively, were placed in high-belief groups and those below the median in low-belief groups. The above procedure yielded a 2 × 2 analysis of variance (ANOVA) design with practice trials and belief in the paranormal as independent variables.

Table 2 (column 1) shows that the number of trials on which subjects were confident of success varied with both the number of practice trials, $F(1, 51) = 16.24$, $p < .001$, $\omega^2 = .194$, and with degree of general psychic belief, $F(1, 51) = 10.1$, $p < .005$, $\omega^2 = .116$. The interaction was nonsignificant ($F < 1$).

Table 2 (column 2) shows ratings on the posttask question, "How much do you feel that your concentration influenced what colors came up on the 20 trials?" We found main effects for the practice trial variable, $F(1, 51) = 4.33$, $p < .05$, $\omega^2 = .05$; and for the general belief variable, $F(1, 51) = 7.72$, $p < .01$, $\omega^2 = .101$. The interaction was nonsignificant, $F(1, 51)$ 2.29, $p > .05$.

Table 2
Estimated Success as a Function of Practice Trials and Prior Belief

Group	Number of confident trials (0–20)	Self-influence estimates (0–9)
1 Practice trial		
Low belief		
M	6.83	1.88
SD	3.74	2.15
High belief		
M	10.14	4.57
SD	3.01	2.21
10 Practice trials		
Low belief		
M	10.87	4.13
SD	3.62	2.53
High belief		
M	13.00	4.93
SD	2.04	2.34

Discussion

This experiment demonstrates the effects of practice and prior belief on judgments of success on a psychic task, without any apparent accompanying psychic ability. These results replicate Ayeroff and Abelson (1976) and support Langer's (1975) illusion-of-control model.

Experiment 3: Involvement

We sought further confirmation of the hypothesis that people given a skill orientation would judge their performance on a PK task more positively than those not given this orientation. Subjects run in pairs were either actively or passively involved in the PK task. We predicted that active subjects would perceive more control over the task than passive subjects. We also attempted to replicate the effect of general paranormal belief on estimated PK performance.

Method

Subjects. Thirty female and 30 male introductory psychology students at California State University, Long Beach, fulfilled a course requirement by participating.

Apparatus. The apparatus was the same as in Experiment 1.

Procedure. Subjects came to the experiment room in same-sex pairs, were given a definition of PK similar to the one given in the previous two studies, and were told that the present investigators were beginning a research program on PK. Subjects were then asked to inspect the die funnel, after which they were told that the experiment called for both members of each pair to explore at the same time the possible effects that two persons have on the throw of a die. They were also told that although they both were to try to affect the outcome of each die toss, only one of them would actually toss the die. Experimenter A randomly chose one of the subjects to throw the die and then asked both to sit at predetermined spots at one end of the die funnel. Subjects were separated by a partition so that they could not see each other's responses on the confidence checklist.

The painted die used in Experiments 1 and 2 was again produced for the subjects to inspect. During this process, subjects were read instructions similar to those given in Experiments 1 and 2, asking them to center and concentrate their full mental energies for a period of 10 seconds on affecting the color called. Also, Experimenter A instructed subjects on how to complete the confident/not confident checklists. The sequence of target colors was constant across conditions.

On each of 14 trials, both subjects concentrated on making the target color land face up, one subject then threw the die, and finally both responded to the confident/not confident checklist. Following the last trial, Experimenter A left the room after indicating that a coexperimenter would arrive shortly. Experimenter B entered, blind to the condition experienced by the subjects, and administered two questionnaires. Questionnaire 1 consisted of two questions constructed on a Likert-format scale. The first asked, "How much do you feel that *your* concentration influenced what colors came up on the 14 trials? That is, how much psychokinetic control do you feel you had?" The second question asked, "How much do you feel the *other* person's concentration influenced what colors came up on the 14 trials? That is, how much psychokinetic control do you feel the other person had?" The order of presentation of the questions was reversed for different subjects. Questionnaire 2 asked subjects to judge on a Likert-format scale the extent to which they believed in psychic phenomena: "Do you believe that people possess psychic abilities, such as ESP and PK?"

Results

The mean success rate for subjects was 7.1. The results of all analyses attempting to show PK effects may be summarized succinctly—no PK effects were found.

As in Experiment 2, we generated high- and low-psychic-belief groups within the active and passive conditions. The median scores on the general belief question for the active and passive conditions were 6 and 7, respectively. Within each condition, subjects scoring above the median were placed in a high-believer group and those scoring below the median were placed in a low-believer group.

Judgments of success varied across the involvement conditions. Table 3 (column 1) shows that active subjects were confident on more trials than were passive subjects, and an ANOVA on these data shows this difference to be significant, $F(1, 59) = 11.10$, $p < .005$, $\omega^2 = .147$. No other significant differences were found (Fs < 1).

An ANOVA was performed with high/low belief and active/passive involvement as between-subjects variables and the self/other perceived-influence questions as a within-subject variable, the dependent measure being the rating on the self/other questions. There was no significant main effect for belief ($F < 1$). There was a significant main effect for the self/other variable such that subjects rated their own control over the die to be greater than that of their partners, $F(1, 56) = 11.21$, $p < .005$, $\omega^2 = .09$. Similarly, active subjects gave higher ratings than passive subjects, $F(1, 56) = 4.23$, $p < .05$, $\omega^2 = .04$. The above main effects must be qualified in light of a significant Active/Passive × Self/Other interaction, $F(1, 56) = 10.49$, $p < .005$, $\omega^2 =$ differ, although they were lower than the *self* PK influence ratings relative to their *other* PK influence ratings (see Figure 1). The *self/other* ratings for passive subjects did not differ, although they were lower than the *self* ratings of active subjects. No other significant interactions were found.

Discussion

Active subjects were confident on significantly more trials than passive subjects (cf.

Table 3
Estimated Success as a Function of Involvement and Prior Belief

Group	Number of confident trials (0–14)	Self-influence estimates (0–9)	Other influence estimates (0–9)
Passive involvement			
Low belief			
M	7.06	2.59	2.53
SD	2.46	2.15	2.15
High belief			
M	7.62	3.58	3.38
SD	1.19	2.07	1.56
Active involvement			
Low belief			
M	8.73	4.73	3.13
SD	1.58	2.34	2.00
High belief			
M	8.93	4.87	2.93
SD	1.16	1.46	2.12

Golin, Terrell, & Johnson, 1977; Langer, 1975; Wortman, 1975; Benassi, Roher, & Reynolds, Note 2). The second finding was the significant Self/Other × Active/Passive interaction. In general, when two people are jointly involved with a task, one may feel more responsible for producing an outcome than the partner is only when one is the more active participant in the situation. The fact that our active subjects gave higher *self* than *other* ratings in a chance situation provides further support for Langer's (1975) illusion-of-control model.

Experiment 4: Involvement and Locus of Control

The major purpose of the present study was to determine how persons with an internal or external locus of control respond to a PK task. Rotter (1966) proposed that persons differ in the extent to which they feel control over events, with internals perceiving more control than do externals. Some research is consistent with the notion that internals perceive control over events only when the events are seen as potentially controllable (see Geen, 1976, pp. 242–243). In general terms, internals should perceive control in skill but not chance situations (cf. Miller & Seligman, 1973; Rotter, 1966). Conversely, externals should perceive little control in chance or skill situations. We predicted that active/internals would perceive more control in a situation than active/externals, passive/internals, and passive/externals, who would not reliably differ in their estimated control. In our experiment we induced the perception of skill by making one of a pair of subjects actively involved with the task; the perception of chance was induced by making the other partner a passive participant in the task.

Method

Subjects. Thirty male and 30 female introductory psychology students at California State University, Long Beach, completed a course requirement by participating.

Apparatus and materials. The die funnel was used. Responses to each of the 46 statements from Rotter's (1966) locus-of-control scale were given on a *disagree/agree* format (based on Collins, 1974). Scoring was accomplished by summing subject's ratings to each statement, with higher sums reflecting externality. Scoring was reversed on external items, that is, a rating of 1 was changed to 5, and so forth.

Procedure. Subjects reported to the experimental room in groups of five. The experimenter gave a general introduction similar to that given in Experiment 3. Subjects were told that the experimenter could only work with one subject at a time, and they were asked to complete an attitude questionnaire (the locus-of-control scale) while waiting for

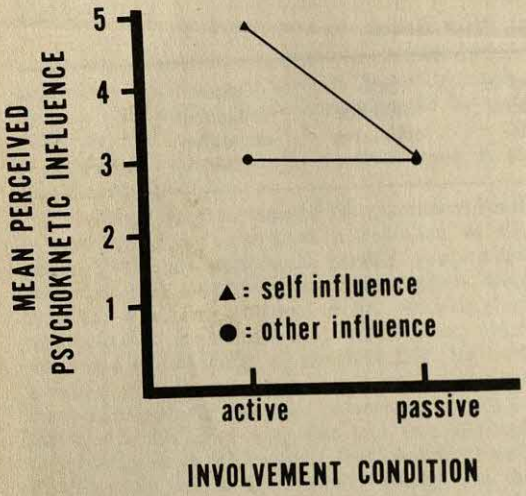

Figure 1. Active/Passive × Self/Other interaction.

their turns. Before the questionnaire was completed, a "lottery" chose one subject to serve as the experimenter's helper; the lottery was manipulated so that a confederate of the experimenter was always selected.

The four real subjects were given time to complete the questionnaire. Next, they were individually put through the following experimental procedure, similar to that of Experiment 3. The subject was given a target color; he or she concentrated on producing the target for 10 seconds; the die was thrown; the subject verbally indicated on a 0-to-10 scale his or her degree of confidence that the target color had come up. The confederate recorded the confidence ratings and the outcome of each die toss. In one condition, the subject threw the die (active involvement); in the other condition, the experimenter threw the die (passive involvement). Each subject received 20 trials with a constant sequence of target colors. Neither the experimenter nor the confederate was informed about the purpose of the study until all subjects had been run.

Results

The data of the 10 most internal and 10 most external subjects from the active and passive conditions were analyzed. The rationale for this decision was that we wished to create more extreme groups on the locus-of-control dimension than would probably have resulted if we had created groups by doing a median split on the locus-of-control scores. Table 4 (row 1) shows the mean locus-of-control scores for each of the Locus of Control × Involvement groups.

The hit rates for the experimental groups did not reliably differ from each other ($F < 1$). Also, no group reliably deviated from chance performance (Table 4, row 2).

Each subject's confidence rating was obtained by taking the mean rating for the 20 test trials. Table 4 (row 3) shows that active subjects were more confident than passive subjects, $F(1, 36) = 4.02$, $p < .06$, $\omega^2 = .06$. Internals gave nonsignificantly higher ratings than externals, $F(1, 36) = 2.11$, $p > .10$. The predicted interaction did not reach significance, $F(1, 36) = 2.53$, $p > .10$.

The ratings on the posttask measures provided consistent and moderate support for the hypothesized interaction. On the Likert-format question "How much control do you feel you had over what colors came up from the die tosses?" active subjects gave higher estimates than passive subjects, $F(1, 36) = 4.23$, $p < .05$, $\omega^2 = .07$ (Table 4, row 4). Internals gave nonsignificantly higher ratings than externals, $F(1, 36) = 2.75$, $p > .10$. The interaction was marginally significant, $F(1, 36) = 3.70$, $p < .08$, $\omega^2 = .06$. To the Likert-format question "Do you feel you would get better on the task if you were given another 20 trials?" active subjects gave higher ratings than passive subjects, $F(1, 36) = 7.93$, $p < .01$, $\omega^2 = .11$ (Table 4, row 5). Internals were significantly more confident than externals, $F(1, 36) = 8.73$, $p < .01$, $\omega^2 = .13$. The interaction was significant, $F(1, 36) = 7.18$, $p < .02$, $\omega^2 = .10$. To the question "If you were given another 20 trials, how many do you think you would get?" active subjects gave nonsignificantly higher ratings than passive subjects, $F(1, 36) = 3.14$, $p > .1$ (Table 4, row 6). Internals gave higher ratings than externals, $F(1, 36) = 5.99$, $p < .02$, $\omega^2 = .09$. The interaction was significant, $F(1, 36) = 8.72$, $p < .01$, $\omega^2 = .14$.

Discussion

Active subjects gave higher estimates of their performance, replicating Experiment 3 as well as previously cited research. Internals gave higher ratings than externals on two of the four dependent measures. These results should be qualified, however, in light of the

Table 4
Summary of Data From Experiment 4

Measure	Active		Passive	
	Internals	Externals	Internals	Externals
Locus of control				
M	120.80	150.80	118.40	151.40
SD	10.95	4.38	12.69	6.83
Hit rate				
M	9.80	10.10	10.00	9.80
SD	2.80	2.28	1.83	2.40
Confidence (0–10)				
M	6.20	4.00	3.60	3.70
SD	1.61	2.16	2.87	2.31
Perceived control (0–10)				
M	4.90	2.20	1.90	2.10
SD	2.86	2.25	2.28	2.07
Improvement (0–10)				
M	6.10	2.00	2.10	1.90
SD	2.72	1.86	2.76	1.60
Another 20 trials				
M	13.10	9.90	10.30	10.60
SD	2.51	1.79	1.63	1.34

Note. For each dependent variable, a one-way ANOVA was done on the results of the active/external, passive/internal, and passive/external groups; all *F*s were less than 1. Next, for each measure, the data from these groups were collapsed and compared with the data of the active/internal subjects by way of *t* tests for independent means. Each comparison showed a difference between means at the $p < .001$ level of significance for a two-tailed test.

significant Involvement × Locus of Control interaction obtained on three of the four dependent measures. Comparison of the mean values in Table 4 shows that active/internals gave consistently higher estimates of their performance than subjects in the other three experimental groups, whose estimates did not reliably differ from one another. Internals seem to detect the presence or absence of skill cues and then attempt to exert control if skill is perceived as possible. In our experiment, skill was merely illusory. While an internal locus of control is viewed as a positive characteristic in many contexts, internals who threw the die manifested the highest degree of superstitious behavior among our subjects.

In a study similar to ours, Miller and Seligman (1973) failed to find a main effect for locus of control or a Locus of Control × Task (chance vs. skill) interaction. Differences between the studies make it difficult to account for these discrepancies. Miller and Seligman, for example, assigned subjects to internal or external groups based on a median split done on responses to Rotter's (1966) forced-choice scale. Also, they gave subjects bogus feedback after each trial of their skill and chance tasks. Lastly, they used different tasks for their skill and chance conditions.

General Discussion

In the present studies the situational variables of instructional set, practice, and involvement affected estimated success on a PK task independent of actual success. Similarly, general belief in paranormal phenomena and locus of control orientation was significantly related to estimated performance. The locus-of-control variable was found to interact with the involvement variable in Experiment 4. The results of Experiments 1–4 are consistent with Langer's (1975) skill theory of nonveridical perceived control. The fact that the theory was supported in a psychic context

using a variety of independent and dependent variables bolsters the theory's generalizability.

The consistent pattern of interaction found in Experiment 4 demonstrates the relevance of the locus-of-control construct for a theory of nonveridical perceived control. Externals actively involved with the task gave no higher estimates of their performance than either internals or externals passively involved with the task. Thus, being actively involved in a chance task may evince no greater estimate of performance than would be made after being passively involved with the task, *unless* the person has an internal locus of control. Future work might determine whether the effects of locus-of-control orientation could be overriden in contexts different from ours.

Langer's (1975) skill theory is a cogent account of how illusions of control can be induced. At the same time, the phenomenon of illusory control is sufficiently complex that it cannot as yet be accounted for by a single model. Future research might profitably focus on the following factors, which may be shown to be related to perceived illusory control: human biases in information processing (Kahneman & Tversky, 1973)[3]; coincidences, particularly dramatic (psychic?) ones; the human propensity to recall successes and to forget or play down failures (Ward & Jenkins, 1965); personality variables such as locus of control, need for certainty, and so forth. We are inclined to speculate that the same variables that affect one's judgment of personal control also affect one's judgment of another's control. Also, we suspect that the emotional concomitants associated with perceived psychic control are noticeably greater than those correlated with more mundane perceived control. For whatever reasons, the realm of the paranormal seems to conjure deep-seated emotional reactions that far exceed those warranted by the phenomena on which they are based. We plan to examine these speculations in our future work.

[3] In a manuscript in preparation, the first author found that in judging another's success on a psychic task, students fell prey to the availability and representation fallacies described by Kahneman and Tversky (1973).

Communicator Physical Attractiveness and Persuasion

Shelly Chaiken
University of Toronto, Toronto, Canada

In a field setting, physically attractive or unattractive male and female communicator-subjects delivered a persuasive message to target-subjects of each sex. Results indicated that attractive (vs. unattractive) communicators induced significantly greater persuasion on both a verbal and behavioral measure of target agreement. In addition, female targets indicated greater agreement than did male targets. Data gathered from communicator-subjects during an earlier laboratory session indicated that physically attractive and unattractive communicators differed with respect to several communication skills and other attributes relevant to communicator persuasiveness, including grade point average, Scholastic Aptitude Test scores, and several measures of self-evaluation. These findings suggest that attractive individuals may be more persuasive than unattractive persons partly because they possess characteristics that dispose them to be more effective communicators.

Experimental evidence regarding the effect of communicator physical attractiveness on persuasion is equivocal. Although two studies have demonstrated that attractiveness can significantly enhance a male communicator's persuasiveness with both male and female message recipients (Horai, Naccari, & Fatoullah, 1974; Snyder & Rothbart, 1971), the majority of published experiments have failed to obtain significant attractiveness effects or have obtained interactions between attractiveness and other variables (Chaiken, Eagly, Sejwacz, Gregory, & Christensen, 1978; Mills & Aronson, 1965; Blass, Alperstein, & Block, Note 1). For example, Mills and Aronson (1965), using a female communicator and male recipients, found no overall effect of communicator attractiveness on persuasion. However, on a marginally significant basis, they did find that the communicator's expression of a desire to influence recipients enhanced her persuasiveness when she was attractive but not when she was unattractive. Blass, Alperstein, and Block (Note 1), who also studied a female communicating to male recipients, found that communicator attractiveness and race interacted to affect opinions. A white communicator was more persuasive if attractive than if unattractive, whereas a black communicator was more persuasive if unattractive. Finally, one experiment reported by Chaiken, Eagly, Sejwacz, Gregory, and Christensen (1978) indicated that the persuasive impact of attractive communicators depended both on the sexual composition of the communicator–recipient dyad and on whether recipients anticipated interacting with the communicator. Their second experiment, which employed the identical stimulus materials but utilized a somewhat different cover story, yielded no significant persuasion findings involving the attractiveness variable, however.

All of these experiments were conducted in laboratory settings and all employed experimental manipulations of communicator attractiveness. The majority of studies have

The author is grateful to Alice H. Eagly, Jonathan L. Freedman, and an anonymous reviewer for their comments on an earlier draft of this manuscript, and to John W. Fee III, Herschl Forman, Gerry Johnson, John Keenan, and Aaron Moscoe for their assistance during various phases of the research. A preliminary version of this article was presented at the meeting of the Eastern Psychological Association, Washington, D.C., 1978.

used pictured communicators, varying appearance by means of photographs scaled for physical attractiveness (Chaiken et al., 1978; Horai et al., 1974; Snyder & Rothbart, 1971). Two experiments have utilized either live communicators (Mills & Aronson, 1965) or videotaped communicators (Blass et al., Note 1) whose appearance was varied by means of makeup, dress, and grooming.

The present research addressed two general concerns raised by previous empirical work. The first deals with the importance of the attractiveness cue outside the laboratory. The lack of consistent findings across previous experiments—particularly the paucity of attractiveness main effects and the occurrence of unpredicted and often theoretically ambiguous interactions (Chaiken et al., 1978; Blass et al., Note 1)—suggests that the persuasive impact of physical attractiveness may be far from robust. This concern is heightened by the possibility that the highly controlled settings of previous experiments made the attractiveness cue more salient than it would typically be in more naturalistic settings, and the context of these experiments may therefore have inflated the importance of this variable as a determinant of persuasion. In this regard, it is interesting to note that both experiments demonstrating an attractiveness main effect on opinion change (Horai, Naccari, & Fatoullah, 1974; Snyder & Rothbart, 1971) used photographic stimuli and employed relatively simple experimental procedures. In contrast, studies that have not demonstrated this main effect have used live or videotaped communicators (Mills & Aronson, 1965; Blass et al., Note 1) or have employed relatively more complex experimental procedures (Chaiken et al., 1978, Experiment 1).

Conversely, it might be that previous empirical findings underestimate the importance of the attractiveness variable in persuasion. The implicit demands of the laboratory may encourage subjects to adopt a highly logical mode of cognitive functioning. At the same time, such demands may discourage subjects from utilizing information such as physical attractiveness, which popular wisdom would hold to be irrelevant. Thus, although attractiveness may well influence opinion change in naturalistic settings, the psychology laboratory may provide a particularly unsuitable setting for demonstrating such an effect.

In sum, one concern of the experiment dealt with the importance of communicator attractiveness as a determinant of persuasion. To address this concern, the experiment utilized live, physically attractive and unattractive communicators who delivered a persuasive message to targets in a field setting. It was predicted that attractive communicators would be more persuasive than unattractive ones. No hypotheses were formed with respect to whether *attractiveness* might interact with *communicator* or *target sex* to affect opinions, although some previous findings (Chaiken et al., 1978, Experiment 1) suggest this possibility.

The second concern of the present research, one that presupposes that attractiveness does influence persuasion, deals with the explanation of attractiveness effects. In previous studies, the style in which the persuasive message is presented to subjects has remained constant across experimental conditions. In addition, excluding trait inferences that subjects make, the (typically hypothetical) communicators in these studies are equated on attributes other than attractiveness. Such standardization is of obvious value, since it allows one to conclude that observed differences in treatment are a product of the attractiveness cue rather than the result of some factor that is unintentionally confounded with the attractiveness manipulation. This type of design has been and should be used to evaluate a variety of explanations for the facilitating effect of attractiveness on persuasion, including psychological mechanisms such as credibility enhancement, identification (Kelman, 1961), social reinforcement, cognitive balance, and classical conditioning. However, such designs preclude from consideration the possibility that attractive and unattractive individuals are differentially persuasive because attractiveness is correlated with other attributes that affect communicator persuasiveness.

While little is currently known about actual differences between physically attractive and unattractive persons, researchers (Berscheid & Walster, 1974) have argued that because of differing socialization experiences (e.g., Clifford & Walster, 1973; Dion, 1972) attractiveness may be confounded with other attributes (e.g., intelligence, status, self-concept, personality). Consistent with this argument, Goldman and Lewis (1977) recently reported that attractive individuals may possess greater social skill than unattractive persons. The idea that attractiveness covaries naturally with other factors suggests that attractive individuals may be more persuasive than unattractive persons partly because they possess communication skills or other attributes that dispose them to be particularly effective communicators. To explore this possibility, the present study selected 17 different *communicator-subjects* to represent each of four possible combinations of communicator attractiveness and sex. Videotapes of these communicators delivering the persuasive message were examined to determine possible individual differences in communication skills. The skills measured in the experiment included those identified by previous research (speech rate, Miller, Maruyama, Beaber, & Valone, 1976; nonfluencies, McCroskey & Mehrley, 1969; vocal confidence, London, 1973; eye gaze, Mehrabian & Williams, 1969) or suggested by intuition (smiling) as correlates of communicator persuasiveness. To examine differences with respect to other attributes relevant to persuasiveness, communicator-subjects also completed the Rotter (1966) Internal–External Locus of Control Scale, rated themselves on a series of evaluative scales, and reported their grade point averages and Scholastic Aptitude Test (SAT) scores.

Method

Subjects and Overview of Design

A total of 110 male and female University of Massachusetts undergraduate psychology students participated for extra course credit as communicator-subjects. In a laboratory session immediately preceding their field participation, these individuals were trained to deliver a persuasive message, and their final practice performances were videotaped. In addition, communicator-subjects completed a questionnaire and were photographed. In the field, each communicator delivered the persuasive message to 2 University of Massachusetts undergraduates of each sex. Subsequently, an independent group of judges ($n = 56$) rated communicator-subjects' photographs on physical attractiveness (15-point scale). Communicator-subjects were rank ordered according to their mean attractiveness ratings, and those in the top or bottom third of the distribution for their sex were selected for inclusion in the design. This procedure resulted in the analysis of data from 68 communicators (17 per sex/attractiveness level) and 272 target-subjects (2 male and 2 female targets per communicator). Mean attractiveness scores for the four communicator groups were 8.80 (male/attractive, 9.09 (female/attractive), 6.10 (male/unattractive), and 6.34 (female/unattractive).

Laboratory Procedure

Communicator-subjects were recruited for an experiment entitled "social influence" and were scheduled individually for their laboratory sessions. The (male) experimenter informed communicators that they would be trained to deliver a persuasive message and would then attempt to persuade students whom they would approach on campus. Communicators were told that "in order to explore correlates of communicator persuasiveness," they would complete a questionnaire, be photographed, and be videotaped delivering the persuasive message.

After this introduction subjects completed the first part of a questionnaire on which they indicated their sex, age, grade point average, SAT scores, and agreement (7-point scale) with the position advocated in the persuasive message. Subjects completed the remaining three sections of the questionnaire in one of six possible orders. One section consisted of the 23-item (plus fillers) Internal–External Locus of Control Scale (Rotter, 1966). In a second section, subjects described themselves on 7-point bipolar adjective scales. Positive poles of the 17 scales used were *intelligent, interesting, assertive, confident, likable, knowledgeable, competent, sincere, physically attractive, modest, moral, persuasive, trustworthy, warm, attractive, friendly,* and *sensitive.* Finally, a third section asked subjects to "speculate about their future" by responding on 7-point scales to the following items: *to have an excellent* (vs. *poor*) *job, have a happy* (vs. *drab*) *family life, be regarded as a successful* (vs. *unsuccessful*) *person, be a contented* (vs. *discontented*) *person, be well-off financially* (vs. *in bad financial straits*), *be enjoying life* (vs. *depressed about things*), *be famous for something* (vs. *a very ordinary person*), *be a highly* (vs. *only moderately*) *educated person, be a confident* (vs. *a worried*) *person.*

Subjects next received a script containing the persuasive message as well as all procedural details pertaining to their field participation. To standardize communicator-subjects' training as much as possible,

the following procedure was employed. The experimenter twice went through the field procedure with each subject, once playing the role of communicator and once playing that of target-subject. Communicator-subjects were then allotted 10 minutes to practice the script on their own. Afterwards, the experimenter again went through the script twice with the communicator-subject, both times playing the role of target-subject.

Next, communicator-subjects were asked to deliver the persuasive message "just as you would to a real target-subject." This performance was delivered to an experimental assistant (male) and was videotaped. Subsequently the videotapes were scored by two independent judges (blind to the experimental hypotheses). Exposed only to the audio component of the videotape, each judge rated the communicator's vocal confidence (5-point scale). Using a digital stop-clock, judges recorded the time that the communicator gazed directly at his or her target (experimental assistant) and, to assess speech rate (seconds per word), recorded the time each communicator took to deliver the 111-word persuasive message. A smiling index (possible range 0 to 5) was obtained by having judges record the presence (1) or absence (0) of smiling in each of five segments of the message. Judges also counted the number of nonfluencies (vocal pauses within sentences, repetitions, "umms," "ers," stuttering, etc.) made during delivery of the message. Finally, judges rated the communicator's physical attractiveness (5-point scale) while exposed only to the video component of the tape. For each of the above measures, the two judges' ratings were averaged to obtain a score for each communicator-subject. Interrater reliability coefficients were speech rate, $r = .99$; vocal confidence, $r = 79$; gaze, $r = .99$; smiling, $r = 83$; nonfluencies, $r = .90$; physical attractiveness, $r = .67$.

Just prior to leaving the laboratory for the field, communicators were photographed in a standard pose. The $3\frac{1}{2} \times 5$ inch black and white photographs showing a head and shoulder view of each communicator were subsequently scaled for physical attractiveness by an independent group of judges (see above).

Field Procedure

Each communicator was randomly assigned to one of five campus locations and was then taken to that location by the experimenter. To prevent communicators from selecting their own target-subjects, each communicator was required to approach *every* passer-by until he or she had completed the entire field procedure with 2 university students of each sex. This rule was subject to the following constraints: (a) sex of person approached was required to alternate, (b) only persons walking alone were to be approached, and (3) an approach could not be initiated while the communicator was occupied with another target-subject.

The communicator introduced himself or herself to the target-subject and requested that the target complete an opinion survey. If the target agreed, the communicator stated that he or she was in a campus group favoring the proposition that "the University should stop serving meat at breakfast and lunch at all dining commons," and the communicator supported this position with two brief arguments. After restating the position, the communicator gave the target a confidential questionnaire to complete. On this questionnaire, targets indicated their agreement (7-point scale) with the message's overall position and rated the communicator's friendliness, knowledgeability, and attractiveness (15-point scales). Targets also indicated their sex and age and responded to some filler items designed to make the questionnaire appear to be an opinion survey. Afterwards, targets placed the completed questionnaire in a box provided by the communicator. The communicator next stated that he or she was also circulating a petition demanding that "the University stop serving meat at breakfast and lunch at all dining commons," and asked the target to sign it. After the target had signed (or refused to sign), he or she was thanked for participating in the survey.

Throughout the entire field procedure, the experimenter stood nearby and monitored all communicator–target interactions. Data from 6 (of the initial 110) communicators were excluded from consideration because they deviated greatly from the experimental script (4) or informed one or more of their targets that they were participating in an experiment (2). The experimenter also recorded the total number of approaches required by each communicator in order to complete the field procedure successfully with two male and two female targets.

Results and Discussion

Data provided by target-subjects were analyzed by four-way multivariate and univariate analyses of variance with 2 levels each of communicator sex, attractiveness, and target sex, and 17 levels of communicator (nested within communicator sex and attractiveness). Data from communicator-subjects were analyzed by two-way multivariate and univariate analyses of variance with 2 levels each of communicator sex and attractiveness.

Check on Experimental Design

The attractive communicator-subjects of the present study were clearly perceived as more physically attractive than their unattractive counterparts. An analysis of attractiveness ratings made by photograph judges revealed only an attractiveness main effect ($p < .0001$), as did an analysis of attractive-

Table 1
Mean Target Agreement and Proportion of Targets Signing Petition as a Function of Communicator Attractiveness, Communicator Sex, and Target Sex

Variable	Attractive communicator				Unattractive communicator			
	Male		Female		Male		Female	
	Male target	Female target	Male target	Female target	Male target	Female target	Male target	Female target
Target agreement	4.50	3.32	4.24	3.53	4.91	4.00	4.53	4.03
Petition signing	.29	.53	.35	.47	.35	.38	.24	.29

Note. On the agreement measure, lower numbers indicate greater agreement with the position advocated in the persuasive message. Cell $n = 34$.

ness ratings made by videotape judges' ($p < .001$). Further, targets-subjects perceived physically attractive (vs. unattractive) communicators as more attractive ($p < .05$). It should also be noted that communicator-subjects did not differ significantly as a function of attractiveness or sex with respect to their age or opinions on the persuasive message topic.

Field Data

The five target-subject variables (agreement, petition signing, perceptions of communicator friendliness, knowledgeability, and attractiveness) were first submitted to a four-way multivariate analysis of variance and were then analyzed on a univariate basis.[1] The multivariate analysis yielded significant effects due to communicator sex, $F(5, 60) = 2.96$, $p < .02$, and target sex, $F(5, 60) = 3.16$, $p < .02$, and a marginal effect due to communicator attractiveness, $F(5, 60) = 1.74$, $p < .14$.[2] The univariate analyses revealed that the communicator-sex, target-sex, and communicator-attractiveness main effects attained significance on one (attractiveness), two (agreement, petition signing), and three (agreement, petition signing, attractiveness) of the five target variables, respectively. The remainder of this section presents the results of these more informative univariate analyses.

Persuasion measures. Analysis of targets' agreement with the communicator's overall position (see Table 1) revealed main effects due to communicator attractiveness and target sex. Attractive communicators elicited greater agreement from targets than did unattractive communicators ($M = 3.89$ vs. $M = 4.37$), $F(1, 64) = 4.23$, $p < .05$, and female targets expressed greater agreement than male targets ($M = 3.72$ vs. $M = 4.54$), $F(1, 64) = 11.22$, $p < .005$. No other effects were significant on this measure. Dunnett's test (cf. Myers, 1972) indicated that all experimental groups (in the Communicator Sex × Communicator Attractiveness × Target Sex design) differed significantly from an opinion-only group of pilot subjects[3] in the direction of greater

[1] Following Lunney (1970) and the advice of an anonymous reviewer, the dichotomous petition-signing measure (coded 0,1) was included in the multivariate analysis and was also treated by univariate analysis of variance. The latter analysis yielded main effects due to communicator attractiveness, $F(1, 64) = 3.95$, $p < .06$, and target sex, $F(1, 64) = 5.07$, $p < .05$. These univariate results parallel those presented in the text, which are based on a more conventional treatment of dichotomous data.

[2] Since the nested communicator factor accounted for no significant effects in the four-way analysis, it was ignored in a subsequent three-way multivariate analysis on the five field measures. The three-way analysis, which employs an error term with greater degrees of freedom than the error terms utilized in the four-way hierarchical design analysis, yielded comparable findings: significant effects due to communicator sex, $F(5, 260) = 3.80$, $p < .005$, and target sex, $F(5, 260) = 2.93$, $p < .02$, and a marginal effect due to communicator attractiveness, $F(5, 260) = 1.83$, $p < .11$.

[3] Pilot subjects ($n = 18$) were approached by the experimenter at various campus locations and were

agreement with the position advocated in the message ($ps < .05$ or smaller).

The proportion of targets in each experimental condition who signed the communicator's petition was computed (see Table 1), and z tests were performed on the arcsin transformations of these proportions (cf. Langer & Abelson, 1972). Paralleling the agreement results, this analysis revealed that a greater proportion of targets signed the petition when the communicator was attractive ($p = .41$) rather than unattractive ($p = .32$), $z = 1.56$, $p < .06$, one-tailed, and a greater proportion of female (vs. male) targets signed ($p = .42$ vs. $p = .31$), $z = 1.91$, $p < .06$, two-tailed. No other effects were significant on petition signing.

It should be noted that communicators approached an average of 6.04 individuals in their efforts to deliver the persuasive message to the requisite number of targets. An analysis of the number of approaches that each communicator made yielded no significant effects. Thus male and female and attractive and unattractive communicators were equally successful in gaining the audience of targets.[4]

Other measures. In addition to the significant attractiveness effect on targets' attractiveness ratings, attractive communicators were perceived as somewhat friendlier than unattractive ones ($p = .07$). Finally, targets (unlike either videotape or photograph judges) rated female (vs. male) communicators as more attractive ($p < .001$). No other effects were significant on these measures, and no effects were obtained on targets' ratings of communicator knowledgeability.

The field data generally substantiate the physical attractiveness – persuasion relationship. On both a verbal and behavioral measure, target-subjects expressed significantly greater agreement with attractive, rather than unattractive, communicators. Although the study was not designed to evaluate possible psychological mechanisms underlying this effect, the fact that that targets' perceptions of communicator knowledgeability were unaffected by attractiveness suggests that attractiveness effects in persuasion are not typically mediated by differential perceptions of credibility (also see Norman, 1976; Snyder & Rothbart, 1971). On the other hand, the finding that targets' perceptions of communicator friendliness were marginally affected by attractiveness is consistent with psychological mechanisms such as identification (Kelman, 1961), social reinforcement, cognitive balance, and classical conditioning.

Target sex also had a significant impact on persuasion. Females expressed greater agreement with the communicator's message than did males. While not anticipated, this finding is consistent with two hypotheses recently proposed by Eagly (1978). One hypothesis is that heightened female influenceability may be observed when the message topic is biased against the expertise or interests of women. In view of pilot-subjects' ratings (see Footnote 3), it seems unlikely that the sexes were differentially expert on the meat topic. However, while this study did not assess involvement with the issue, recent findings obtained by Eagly (Note 2) indicate that males may be more interested in or involved with the meat question, perhaps because they are greater consumers of beef than are females. Since greater involvement typically decreases persuasion (e.g., Miller, 1965; Sherif & Hovland, 1961), the present findings are consistent with the idea that male targets' greater involvement with the message topic made them less willing than females to yield to the persuasive message. Eagly's second hypothesis suggests that heightened female influenceability may be observed in situations characterized by the communicator's physical presence

asked to indicate their agreement (7-point scale) with a variety of opinion statements and to judge whether males or females were more expert with respect to each opinion issue (7-point scale). The meat topic was chosen because pilot subjects disagreed strongly with the position advocated in the persuasive message ($M = 6.50$) and considered males and females equally expert on the issue ($M = 4.08$). Further, male and female pilot subjects did not differ significantly with respect to either their agreement or their expertise ratings, $ts(16) < 1.0$, on this issue.

[4] Of the 411 individuals approached by the study's 68 communicators, 139 (34%) refused the communicators' initial requests that they "complete an opinion survey."

and surveillance, and may be a product of females' greater concern with maintaining social harmony and insuring smooth interpersonal relations. The fact that a sex difference occurred in this experiment where communicators presented their messages to targets during face-to-face encounters is also compatible with this hypothesis.

As Eagly (1978) has noted, differences in interpersonal orientation as an explanation of sex differences in influenceability imply that the greater persuasibility of women may represent surface agreement rather than genuine belief change. Yet, if this explanation is entertained, the meaning of the experiment's persuasion measures and of the observed attractiveness effects is called into question. Did the greater "persuasion" induced by attractive (vs. unattractive) communicators represent genuine belief change or mere compliance? Although a compliance interpretation cannot be completely ruled out, at least two aspects of the field data favor the idea that communicator attractiveness did actually effect genuine changes in targets' opinions. First, unlike the petition-signing measure, communicators did not see targets' verbal agreement responses. Targets were told that their opinions were confidential, and targets themselves inserted their completed questionnaires in a ballot box provided by the communicator. Yet this measure, which should have been less susceptible to compliance pressures, showed an attractiveness effect of the same (and slightly higher) magnitude as that shown on petition signing. Second, a compliance interpretation suggests that attractive (vs. unattractive) communicators should have been more successful in inducing compliance with their initial requests that potential targets "complete an opinion survey." However, analysis on the number of approaches made by each communicator revealed no attractiveness effect ($p > .65$).

Individual Differences Between Communicator-Subjects

A second focus of the experiment was to investigate whether the greater persuasiveness of physically attractive communicators might be understood in terms of differences between attractive and unattractive individuals on dimensions relevant to communicator persuasiveness. The individual difference measures obtained during communicators' laboratory participation were first submitted to a two-way (Attractiveness × Sex) multivariate analysis of variance and were then analyzed on a univariate basis. The multivariate analysis yielded only an attractiveness main effect, $F(36, 29) = 9.52$, $p < .001$. However, the univariate analyses revealed that this effect attained significance or marginal significance on only a small proportion of variables. The remainder of this section presents the findings of these univariate tests.

Communication skills. Analyses on the communication skills measured in this study revealed that compared to unattractive communicators, attractive communicators were significantly more fluent speakers ($p < .05$) and had a marginally faster rate of speech ($p = .07$). Attractive and unattractive communicators did not differ with respect to vocal confidence, gaze, or smiling. The only other effects on these variables were due to communicator sex. Male (vs. female) communicators spoke faster ($p < .05$) and smiled less ($p < .001$) while delivering the message.

Other attributes. Phares (1965) found that students who were more internal (vs. external) in their locus-of-control orientation (Rotter, 1966) were more successful in influencing other students' attitudes. And Miller (1970) has shown that attractive (vs. unattractive) persons are perceived by others as being more internal. In the present study, an analysis of communicators' locus-of-control scores yielded no significant effects. It should also be noted that locus of control was not significantly associated with an index of communicator persuasiveness (sum of targets' agreement scores), $r = -.15$, $p < .20$, although the direction of the relationship is consistent with Phares' (1965) results.

On communicator-subjects' self-reported SAT scores, both an attractiveness main effect ($p < .05$) and a Communicator Attractiveness × Communicator Sex interaction ($p < .05$) were obtained. Overall, attractive communicators reported higher SAT scores

than did unattractive ones. However, this difference was most evident for female (vs. male) subjects. Attractive (vs. unattractive) communicators also reported marginally higher grade point averages ($p = .11$).

Although attractive communicators tended to regard both themselves and their future more positively than unattractive communicators did on many (but not all) of the self-descriptive items, the attractiveness main effect reached significance or marginal significance on only a very few scales. Physically attractive (vs. unattractive) communicators tended to regard themselves as more persuasive ($p < .025$), attractive ($p < .10$), and interesting ($p < .10$), and were somewhat more optimistic about obtaining an excellent job ($p < .10$). These analyses also revealed that female (vs. male) communicators viewed themselves as more moral (vs. immoral; $p < .01$) and indicated more optimism with respect to obtaining an excellent job ($p < .05$) and being a successful person ($p < .05$). Finally, a Communicator Sex × Communicator Attractiveness interaction was obtained on communicators' speculations regarding their future contentedness ($p < .05$). Attractive females and unattractive males speculated that they would be more contented than discontented whereas unattractive females and attractive males speculated that they would be more discontented.

These results indicate that attractive and unattractive individuals do differ on dimensions other than physical appearance. Attractive communicators were more fluent speakers and faster speakers than their unattractive counterparts. Further, attractive communicators tended to report higher scores on two indices of educational accomplishment (grade point average, SAT scores) and described themselves somewhat more favorably along several dimensions (persuasiveness, attractiveness, interestingness, optimism about getting an excellent job) that may tap aspects of self-concept.

The remaining question is whether the differential persuasiveness of physically attractive and unattractive communicators can be understood in terms of the observed differences with respect to communication skills, educational accomplishment, and components of self-concept. Correlations between communicators' scores on these measures and their persuasive effectiveness were generally low and nonsignificant (ps = .07 or higher). Although the relationship between communicators' attractiveness scores and persuasive effectiveness was low to begin with ($r = .20$, $p = .05$), it did attenuate somewhat when the influence of these individual difference measures was removed ($r = .14$, $p = .14$). These results suggest that while the observed individual differences do not provide a full explanation for the observed effect of attractiveness on persuasion, they may have contributed at least partially to this effect. In any case, it would seem premature to discount such individual difference variables as correlates of communicator persuasiveness or, by extension, to discount the role of these variables in understanding the attractiveness–persuasion relationship. Research has demonstrated that both fluent speech (McCroskey & Mehrley, 1969) and speech rate (Miller et al., 1976) relate positively to persuasion. And although little is known concerning the psychology of the persuasive communicator (in contrast to the psychology of the message recipient), it seems reasonable that factors such as self-concept and educational achievement, a frequently used indicant of intelligence, should contribute to one's effectiveness as a social influence agent.

Conclusions and Implications

The present research indicates that physical attractiveness can significantly enhance communicator persuasiveness. A number of aspects of the findings and the experimental design are worth noting, since they suggest that the attractiveness–persuasion relationship may be fairly general. First, the attractiveness effect on persuasion was obtained on both a verbal and behavioral measure, and attractiveness did not interact with either communicator or target sex to affect agreement. Second, the design featured multiple-stimulus persons at every level of communicator attractiveness and sex, and this nested communicator factor accounted for no significant effects in the

analyses of variance. Third, communicator-subjects were not judged to be extreme in physical attractiveness. Thus, the persuasion results were obtained using attractive and unattractive communicators who are probably quite representative of those whom individuals might encounter in their everyday lives. Last, the findings were obtained in a field setting where the salience of information about physical attractiveness should approximate its salience in genuine interpersonal situations and where any implicit experimental demands on the subject to overutilize or underutilize attractiveness information should be minimal.

Despite the study's apparent success in demonstrating the attractiveness–persuasion relationship, a number of issues remain unresolved and require further investigation. First, the interpersonal-orientation explanation of the observed sex differences in persuasibility raises the possibility that the enhanced persuasion induced by attractive communicators may have represented heightened compliance rather than genuine belief change. While the field data seem more compatible with a belief-change interpretation, compliance cannot be completely eliminated as an explanation. Research that manipulated communicator presence and/or surveillance in conjunction with physical attractiveness would be quite useful in resolving this issue. A second issue concerns the psychological mechanisms underlying the attractiveness–persuasion relationship. The results of this experiment as well as those of some previous studies (Norman, 1976; Snyder & Rothbart, 1971) suggest that credibility enhancement does not typically mediate the attractiveness–persuasion relationship. However, mechanisms such as identification (Kelman, 1961), social reinforcement, cognitive balance, classical conditioning, and perhaps others remain possible and require further evaluation.

Finally, there is the question of why most previous experiments have failed to demonstrate the attractiveness effects on persuasion observed here. One answer is suggested by the fact that the attractiveness effects obtained in this study, while statistically reliable, were not very strong. If, as the magnitude of these effects imply, the persuasive impact of attractiveness is not particularly robust, the failure of previous efforts to document such a relationship becomes more understandable. One obvious implication of this explanation is that while physical attractiveness can be a significant determinant of persuasion, it may not be a particularly important determinant. A second possible explanation stems from the laboratory nature of previous research. As suggested earlier, the implicit demands of the psychology laboratory may often lead subjects to adopt highly logical modes of cognitive functioning and, as a consequence, to underutilize attractiveness information in forming their opinions. The ecological validity of the laboratory for studying the attractiveness–persuasion relationship requires further investigation, perhaps through research that explicitly incorporates social-influence setting (field vs. laboratory) as a feature of its experimental design.

Individual Differences Between Attractive and Unattractive Communicators

The experiment also revealed differences between attractive and unattractive communicator-subjects with respect to characteristics relevant to persuasive effectiveness (communication skills, educational accomplishment, components of self-concept). These results provide preliminary evidence that in genuine interpersonal situations, attractive individuals may be more persuasive than unattractive persons because they possess characteristics or skills that dispose them to be particularly effective communicators. In this regard, it should be noted that in a recent investigation of manipulative social influence among children, Dion and Stein (1978) found that attractive and unattractive children were both differentially successful and employed markedly different interaction styles in attempting to influence peers.

Previous investigators have studied physical attractiveness in isolation from, rather than together with, its concomitant variables. The present findings and those of Dion and Stein (1978) underscore the utility of the latter

approach. Future research should address itself to a more systematic investigation of individual differences between the physically attractive and unattractive with respect to variables relevant to social influence. For example, research on the physical attractiveness stereotype indicates that attractive (vs. unattractive) individuals are perceived by others as more likable, friendly, interesting, and poised (cf. Berscheid & Walster, 1974). Such attributes would seem of obvious advantage to someone wishing to influence others. Further research might attempt to assess whether physically attractive people actually behave in a more likable, friendly, interesting, and poised fashion with others—either because they possess these traits or, as Snyder, Tanke, and Berscheid (1977) have recently argued, because the stereotype-based expectations of others tend to elicit and maintain such behaviors—and whether such behaviors can help to explain their greater effectiveness as agents of social influence. In addition to furthering our understanding of the relationship between attractiveness and social influence, such research would provide valuable information regarding the validity of the physical attractiveness stereotype and would also increase our knowledge about communicator characteristics and behavioral styles and their role in social influence.

A Creative Personality Scale for the Adjective Check List

Harrison G. Gough
Institute of Personality Assessment and Research
University of California, Berkeley

The Adjective Check List was administered to seven male and five female samples comprising 1,701 subjects. Direct or inferred ratings of creativity were available for all individuals. The samples covered a wide range of ages and kinds of work; criteria of creativity were also varied, including ratings by expert judges, faculty members, personality assessment staff observers, and life history interviewers. The creativity scales of Domino and Schaefer were scored on all protocols, as were Welsh's A-1, A-2, A-3, and A-4 scales for different combinations of "origence" and "intellectence." From item analyses a new 30-item Creative Personality Scale was developed. It is positively and significantly ($p < .01$) related to all six of the prior measures but surpasses them in its correlations with the criterion evaluations.

Creativity is a valued commodity in every kind of human endeavor. Since the publication of Guilford's (1950) influential presidential address to the American Psychological Association, an enormous amount of effort has been invested in the study of creativity and its determinants. One line of investigation within the larger domain of inquiry has been the search for methods of assessment that can identify creative talent and potential within the individual. Many of these studies have addressed cognitive issues and problem solving. For example, Guilford and his colleagues (Guilford, Wilson, Christensen, & Lewis, 1951) developed a series of tests stressing ingenuity, the ability to overcome constraining sets, and fluency in ideation. Mednick (1962) proposed a method of assessment requiring the generation of remote associations for the solution of analogies.

In regard to intellectual functioning, it should be noted that most studies have found intellectual ability as usually measured to be unrelated to criteria of originality. MacKinnon and Hall (1972) obtained Wechsler Adult Intelligence Scale (WAIS; Wechsler, 1958) protocols from 88 architects, 37 research scientists, 33 male mathematicians, and 27 female mathematicians who had also been rated on creativity. Within each sample, subjects were dichotomized into those with higher or lower ratings. The higher rated subgroup, taken from all four samples, had a mean full-scale IQ of 133, and the lower rated subgroup had a mean IQ of 131. The difference between the means was not statistically significant, nor were there any noteworthy differences in range or dispersal of scores. In their study of gifted students, Getzels and Jackson (1962) found intelligence to play a smaller role than personality in determining creativity, and Taylor (1960) also found general intellectual ability to be less important than special kinds of thinking and motivational factors.

Ordinary observations have long suggested that artistic temperament and aesthetic dispositions are related to creative potential. A landmark study of this hypothesis was that of Barron and Welsh (1952) in which a nonverbal figure-preference scale was introduced. The original Barron-Welsh Art Scale and the Revised Art Scale (Welsh, 1969, 1975), in which *like* and *dislike* responses are balanced, have repeatedly been shown to differentiate between more and less creative persons in various scientific, literary, and artistic fields (Barron, 1972; Welsh, 1977). Another ex-

ample of measurement in the aesthetic domain is the Hall Mosaic Construction Test (Hall, 1972).

Personal traits and dispositions have also been examined in regard to creativity, using both standard personality inventories and specially developed scales and questionnaires. Examples of this kind of work may be found in the writings of Barron (1957, 1958), Domino (1974), Gough (1956/1962, 1976), Helson (1977), Kanner (1976), MacKinnon (1962, 1965), and Stein and Heinze (1960). An overall analysis of intellectual, aesthetic, motivational, and other kinds of tests for creativity has been published by Barron (1965).

A particular topic within the realm of studies of personality is that dealing with the self-concept. The Adjective Check List (ACL; Gough & Heilbrun, 1965) is an assessment device intended for appraising views of the self, and as might be expected it has frequently been employed in investigations of creativity (Cashdan & Welsh, 1966; MacKinnon, 1963; Schaefer, 1969). Several attempts, in fact, have been made to develop creativity scales for the ACL. Schaefer (Smith & Schaefer, 1969) identified 27 items that differentiated between the responses of high school boys rated as more and less creative. Only one of these items (cooperative) was checked more often by those with lower ratings; the other 26 items were more often endorsed by higher rated respondents. Follow-up studies (Schaefer, 1972, 1973) indicated that the scale retained its validity over time.

Domino (1970) asked faculty members of a liberal arts college to identify all male freshmen who had manifested creative ability. Ninety-six students were selected; these students were then matched against 96 unnominated controls on age, IQ, personal adjustment as estimated from the Minnesota Multiphasic Personality Inventory (MMPI), and declared major. In the next year, faculty members were asked to make a special effort to observe the performance of all of these students and to judge which ones had shown evidence of creative ability; this procedure was repeated in the third year. These steps yielded a final sample of 59 creative males and a control sample of 82. For each student, at least three faculty raters completed descriptive ACLs. Composites were formed for the 141 students by assigning a 1 to items checked by two or more raters, and a 0 to items checked by none or by only one observer. An item analysis of the 300 adjectives in the list identified 68 that differentiated between the two subsamples at the .05 level of probability or beyond. Fifty-nine of these were more often used to describe the creative subsample and 9 were used more often to describe the controls. To simplify scoring and analysis, Domino decided to base his scale solely on the 59 items associated with greater creativity. Cross-validation of the scale on the self-report protocols of new samples of males and females produced correlations ranging from .24 to .45 with criterion classifications of creativity.

A third study in which item analyses were made of the ACL was that of Welsh (1975). Two dimensions were first defined, one deriving from intellectual functioning and behavior and termed *intellectence,* and the other deriving from originality and aesthetic sophistication and termed *origence*. The interactive grid for these two dimensions permitted the specification of four types of cognitive functioning (Welsh, 1977). Type 1, high on origence but low on intellectence, was characterized by diffuse, global, and imprecise integration with little or no differentiation. Type 2, high on both origence and intellectence, was characterized by synthesis, organization, and the cathexis of metaphor. Type 3, low on both origence and intellectence, was characterized by fragmentation of elements and overattention to details. Type 4, low on origence but high on intellectence, was characterized by analytic and logical preferences. The four types could be very briefly described as imaginative, intuitive, conventional, and analytic in their cognitive styles. Adjective Check List scales were developed for each quadrant by contrasting the responses of individuals in that cell with those of individuals in the other three. The A-1 scale for respondents high on origence but low on intellectence contained 21 items. The A-2 scale for respondents high on both axes contained 25 items. The A-3 and

A-4 scales contained 17 and 24 items, respectively. Scoring on all four scales was by endorsement only; no points were given for nonendorsement of contraindicative adjectives.

During the late 1950s, the writer directed a study of creativity among research scientists (Gough & Woodworth, 1960). When the six ACL scales described above were applied to the 45 scientists in this study, rather disappointing results were obtained. The correlations with the criterion ratings of creativity were .01 for Domino's scale, .08 for Schaefer's, and −.06, −.01, −.08, and .08 for the four measures developed by Welsh. Similar results were obtained when the six scales were scored on the self-report ACLs of the 57 male mathematicians studied by Helson and Crutchfield (1970). Correlations with criterion ratings of creativity were −.11, −.03, .05, −.08, .05, and −.08 for the six ACL scales, in the same sequence. Because of these inconclusive findings, it was decided to undertake a new analysis of the ACL, using larger samples and a broader range of criteria, to see if a stronger measure could be developed.

Method

Samples

Six male samples were available in which the ACL had been administered and criterion ratings of creativity had been gathered. The first was composed of 124 architects studied by MacKinnon and Hall (Hall & MacKinnon, 1969). The second was comprised of the 57 male mathematicians just mentioned (Helson & Crutchfield, 1970). The third included the 45 research scientists also just mentioned (Gough & Woodworth, 1960). The fourth was a previously unreported sample of 530 graduate students in psychology at Berkeley, tested during the first week of entry and rated 3 or 4 years later. The fifth was a sample of 66 seniors in engineering (Gough, 1976). The sixth was a composite sample of 256 men who had been intensively assessed at the Institute of Personality Assessment and Research and rated by staff observers on creativity. This composite sample included 100 Air Force officers (MacKinnon, Crutchfield, Barron, Block, Gough, & Harris, 1958), 70 medical school applicants (Gough & Hall, 1973), 20 college sophomores from an unpublished study of vocational and career planning, 41 males from a study of population psychology (Gough, 1973), and 25 males from a study of environmental preferences (Craik, Note 1).

There were four samples of women for which ACL protocols and ratings of creativity were available. The first was comprised of the 41 women mathematicians studied by Helson (1971). The second included 335 graduate students in psychology at Berkeley, tested at the time of entry and rated between 3 and 4 years later by faculty members. The third was composed of the 51 college seniors reported on earlier by Helson (1967). The fourth was a composite sample of 126 women, including 20 college sophomores from the study of career planning, 41 women from the study of population psychology, 25 women from the study of environmental preferences, and 40 first-year students of law (LaRussa, 1977).

In addition to these 1,631 subjects, there were 35 males and 35 females for whom ACL protocols were available and who had been interviewed by two psychologists and described by them on the ACL and on Block's (1961) 100-item California Q-set. Although direct ratings of creativity were not obtained, indirect estimates were derived from the ACL and Q-sort portraits furnished by the interviewers, in a way to be described below.

Tests and Criteria

The ACL self-report protocols of all subjects were scored for the creativity scales of Domino and Schaefer and for Welsh's four scales. Four kinds of criterion evaluations were utilized. For the architects, male and female mathematicians, and research scientists, creativity was specified by ratings furnished by expert judges. The validity and reliability of these ratings are discussed in the papers already cited. Ratings by faculty members supplied the criterion for the engineering students, psychology graduate students, and college seniors. The psychology graduate students had entered over a 24-year period. Faculty ratings were obtained every 3 or 4 years, covering students who had entered in the preceding interval. Corrected interjudge reliabilities for these ratings of creativity ranged from .73 to .87, with a median of .77. Equivalent coefficients were found for the engineers and college seniors.

The 256 males and 126 females seen at the institute in intensive programs of assessment were rated on creativity by panels of 10 or more observers. Corrected interjudge reliabilities for these ratings were typically very high, ranging from .80 to .98.

To develop a criterion for the 70 interviewed subjects, the interviewers' checks on five adjectives and placement of five Q-sort items were summed. The five adjectives were *imaginative, insightful, intelligent, original,* and *resourceful.* There were four Q-sort items given positive weighting: *Has a wide range of interests, Appears to have a high degree of intellectual capacity, Thinks and associates to ideas in unusual ways; has unconventional thought processes,* and *Able to see to the heart of important problems.* One Q-sort item was assigned a negative weight: *Is uncomfortable with uncertainty and complexities.* The total score based on these 10 components had a standardized item alpha reliability coefficient of .79.

Analyses

For purposes of item analysis, four subgroups were defined: (a) 558 males from the samples of architects, mathematicians, scientists, engineers, and other assessed males; (b) 530 male graduate students in psychology; (c) 218 females from the samples of mathematicians, college seniors, and other assessed females; and (d) 335 psychology graduate students. Ratings of creativity were converted to standard scores by subsample. Point-biserial coefficients of correlation were calculated between each of the 300 items in the ACL and the criterion standard scores.

Results

Thirty items were selected for inclusion in the Creative Personality Scale (CPS) on the basis of item analysis. Several examples may be given. The item *egotistical* yielded correlations with the criterion ratings of creativity of .17, .06, .08, and .08 in the four subgroups. Although only the first of these coefficients is statistically significant ($p < .01$), all are positive, and the item itself is consonant with prior conceptualizations of the creative personality. The item also appears on Domino's scale. The item *original* produced correlations of .13, .06, .17, and .11. Two of these coefficients are statistically significant ($p < .05$), and the word appears on both the Schaefer and Domino scales. It is also quite clearly consonant with prior conceptualizations of the creative personality.

The item *conservative* had correlations with the criterion of −.16, −.08, −.13, and −.10. Two of these coefficients are significant at the .05 level of probability, and one is significant at $p = .06$. Because of these findings and because absence of the attribute appears to be consonant with previous conceptualizations of the creative personality, the item was retained with a negative weighting. In this way, 18 positive and 12 negative items were selected for the final scale. The positive items were *capable, clever, confident, egotistical, humorous, individualistic, informal, insightful, intelligent, interests wide, inventive, original, reflective, resourceful, self-confident, sexy, snobbish,* and *unconventional.* The negatively weighted items were *affected, cautious, commonplace, conservative, conventional, dissatisfied, honest, interests narrow, mannerly, sincere, submissive,* and *suspicious.* In scoring a protocol, 1 point is given each time one of the 18 positive items is checked, and 1 point is subtracted each time one of the 12 negative items is checked. The theoretical range of scores is therefore from −12 to +18.

The 30 items were then compared with those in the previous six scales. Seven CPS items were found in Schaefer's 27-item scale, all scored in the same direction. Fifteen CPS items were found in Domino's 59-item scale; 14 were scored in the same direction, the exception being *dissatisfied,* which received a negative weight on CPS and a positive weight on Domino's measure. Two CPS items were found to overlap with Welsh's A-1 scale, 5 with his A-2 scale, 1 with his A-3 scale, and 2 with his A-4 measure. Except for *dissatisfied* on A-2, all of these common items were scored in the same direction. Because *dissatisfied* showed these two reversals, attention was redirected to the item analytic data. On the four subgroups the item had correlations of −.02, −.07, −.10, and −.02. Additional analyses were then computed on the male mathematicians, the research scientists, and the college seniors, where the coefficients were −.17, −.36, and −.10. Because of these findings it was decided to retain the item with a negative scoring weight.

The 30-item Creative Personality Scale (CPS) was then scored on all of the samples included in the present study. Alpha coefficient reliabilities were computed on the four subgroups defined for the item analysis. The coefficients were .77 for the male composite group, .73 for the male graduate students, .81 for the female composite group, and .73 for the female graduate students. Means and standard deviations for each sample are given in Table 1. Among the male samples, the highest mean was attained by the research scientists, followed closely by the psychology graduate students. The lowest mean was that for the 35 males in the sample seen in interviews only. Among the females, the highest mean was that for the female graduate students, and the lowest was that for the women seen only in interviews. Where comparisons seem appropriate, as between the two samples of graduate students and the two samples of

interviewed subjects, CPS scores were significantly ($p < .05$), albeit only slightly, higher for males than for females.[1]

Table 2 gives the correlations among the seven ACL scales, computed on the samples of male and female graduate students in psychology. The median coefficients between CPS and each of the other measures were .68 for Domino's scale for creativity, .74 for Schaefer's scale, .42 Welsh's A-1, .51 for Welsh's A-2, .32 for Welsh's A-3, and .32 for Welsh's A-4. For the other measures, the highest median correlations were those of .89 between the Domino and Schaefer scales, .64 between A-1 and the Domino and Schaefer scales, .82 between A-2 and the Domino and Schaefer scales, .64 between A-3 and A-4, and .64 between A-4 and the Domino and Schaefer scales. The presence of the 12 negatively weighted items in CPS appears to be the reason why the other six scales correlate more highly among themselves than they do with CPS.

Table 3 gives the correlations of the seven ACL scales with criterion ratings for creativity. For all seven of the male samples, the highest coefficient each time was that for CPS, and in six of the seven instances the coefficients for CPS were significant at or beyond the .05 level of probability. The exception was the coefficient of .25 for the 45 research scientists, where $p = .097$ in a two-tailed test. The smallest coefficient for CPS was that of .15 for the psychology graduate students, and the largest was that of .42 for the 256 males rated by observers in the various assessments. On

6. Welsh A-4						
Male					—	.34
Female					—	.30
7. Creative Personality						
Male						—
Female						—

Note. All coefficients are statistically significant beyond the .01 level of probability. A-1 = Welsh high origence, low intellectence; A-2 = Welsh high origence, high intellectence; A-3 = Welsh low origence, low intellectence; A-4 = Welsh low origence, high intellectence.

[1] For purely normative purposes, Adjective Check List protocols for 1,121 college females and 760 college males from the author's research files were scored for the new 30-item scale. The mean of 5.03 ($SD = 4.01$) for males was significantly higher ($p < .01$) than that of 3.97 ($SD = 4.34$) for females. This difference suggests that where raw scores on the new scale are used, analyses should be conducted separately for males and females. It should be noted that most studies with the ACL use scale scores that have been standardized by sex.

* $p < .05$.
** $p < .01$.

the first six male samples, higher coefficients for CPS would be expected because these samples were used in the item analyses. The 35 interviewed males, however, were not used in the item studies and therefore constitute a true cross-validating sample. In this sample the only statistically significant coefficient was that of .35 for CPS.

For the five samples of women, the coefficient for CPS was the highest in four instances and statistically significant at the .05 level each time. The exception occurred in the sample of 41 women mathematicians. For these subjects, Welsh's A-3 scale had a statistically significant ($p < .01$) coefficient of −.42, as did his A-4 scale, for which the coefficient was −.40. The coefficient for CPS on this sample was .28, $p = .075$ in a two-tailed test. The last sample reported in Table 3, the 35 women seen only in life history interviews, constituted a true cross-validating sample. For these subjects, there were three statistically significant ($p < .05$) correlations between scales and the derived criterion rating of creativity: .34 for Schaefer's scale, .35 for Welsh's A-4 scale, and .40 for CPS.

In the six male samples from which item-analytic data were drawn, the median coefficient between CPS and the criterion ratings of creativity was .30, and in the small cross-validating sample of 35 males, the correlation between CPS and the inferred rating of creativity was .35. A similar summary for the female samples yielded a median coefficient of .28 for the samples used in the item analyses and a coefficient of .40 for the small cross-validating sample. These samples covered a wide range of ages, kinds of work, and circumstances of testing. They also involved the use of four vantage points in rating creativity; expert judges, faculty members, personality-assessment staff observers, and life-history interviewers. If one-tailed tests of significance are allowed, the new 30-item scale can claim a

statistically significant relationship with every criterion in every sample. If the two-tailed test is used, 10 of the 12 validity coefficients for CPS were significant at the .05 level of probability or beyond. On the basis of these findings, it seems reasonable to conclude that the new scale is a reliable and moderately valid measure of creative potential and that it may properly be included among the scales to be scored on the Adjective Check List.

Conflict and Avoidance in the Helping Situation

S. Mark Pancer, Linda M. McMullen, Randal A. Kabatoff,
Kent G. Johnson, and Carole A. Pond
University of Saskatchewan, Saskatoon, Canada

Two field studies examined avoidance behavior in individuals asked for a charitable donation. Subjects were observed as they walked past a table placed in a tunnel leading to the university library. The first study showed that subjects tended to maintain a greater distance from the table when it was set up as a donation center than when it was not. In addition, subjects maintained greater distances when a female confederate sat at the table than when no one was at the table. Study 2 replicated the findings of Study 1. It found, in addition, that even greater distances were maintained from the table when a handicapped person sat at the table than when the person at the table was not handicapped. This avoidance behavior is discussed with reference to the kinds of conflict inherent in helping situations.

The helping situation is fraught with conflict. Usually there are strong normative pressures to help those in need and to give aid to those who have been innocently victimized (see Harris & Meyer, 1973; Konečni, 1972). Coupled with these pressures, however, are equally strong forces that tend to inhibit helping. Research has shown, for example, that appeals for help often evoke reactance (Jones, 1970). In certain situations, helping may also expose the helper to danger or to the ridicule of others (see Latané & Darley, 1976). Also, costs in time, effort, and money are often involved in giving help.

One consequence of the conflict inherent in many helping situations may be what Schwartz (1970) refers to as a "redefinition" of the helping situation. The individual redefines the situation to perceive himself/herself as less responsible for helping or the situation as less needful of help. This cognitive redefinition of the helping environment serves to reduce the press of social helping norms and thereby lessens the conflict intrinsic to such situations. Such redefinitions may often be difficult to accomplish, however, as demonstrated in the research of Darley and Latané (1968). They report anecdotal evidence of subjects under much emotional stress resulting from not helping someone who was quite obviously in need of help.

Another means of reducing helping-related conflict is simply to avoid such situations. Canvassers for various charities (e.g., Wilsdon, Note 1) have long noted a tendency in potential donors to ignore the existence of the charity worker or even to go some distance out of their way to avoid the donation site. Avoidance is psychologically perhaps the least costly of conflict-reduction strategies, since it spares the person from any cognitive distortions that might have been necessary to redefine the situation.

The purpose of the present study was to demonstrate the avoidance that can occur in helping situations and to determine some of the factors that may influence the extent of this avoidance. In the studies reported, sub-

This research was supported by Grant 3-771-531 from the University of Saskatchewan's Humanities and Social Sciences Research Fund. The authors thank Marvin Brown and Ken McDowell for their comments on earlier drafts of this article. jects were observed as they walked past a table set up in a tunnel connecting the arts and library buildings on a university campus. It was hypothesized that subjects would show greater avoidance of the area around the table when it was set up as a donation center for a well-known charity than when it was not set up in this way.

Another variable examined was the presence or absence of an experimental confederate at the donation table. Research has shown that personal (or even personalized) requests are more effective in eliciting helping. This may be true for a number of reasons. Anonymous or impersonal requests (such as those represented by placing an unattended donation canister on a street corner) may not be perceived to be as strong as personal requests. Also, the person canvassing for donations may serve as a helping model. It has often been demonstrated that models serve to increase helping, presumably by making helping norms more salient (e.g., Bryan & Test, 1967). Although personal requests often elicit more helping, however, they may also produce greater avoidance. They are even more likely than impersonal requests to produce reactance in the potential donor because of the strong normative pressures implied. In addition, being approached or asked for help by a strange person may represent an invasion of one's personal space. Again, while this may produce more helping (Baron, 1978; Baron & Bell, 1976; Konečni, Libuser, Morton, & Ebbesen, 1975), it is also likely to produce more avoidance. The presence of a confederate at the donation table, then, may serve to intensify the conflicting demands present in the helping situation. This may result in an increased level of helping (and therefore a greater tendency to approach the table) or greater avoidance of the donation site.

Study 1

Method

Summary of design. The experiment was a 2 × 2 factorial. Subjects were monitored as they walked past a table that did or did not contain a United Way donation box (donation factor) and at which there was or was not a female confederate seated (person factor). The measure of avoidance was the distance subjects maintained from the table as they walked past.

Subjects. The subjects were 180 people (45 in each of the four experimental conditions) who were randomly selected as they walked through a tunnel that connected the main library to the arts building on the University of Saskatchewan campus. Only subjects walking alone from the library towards the arts building were monitored.

Experimental site. Approximately halfway through the tunnel, a chair and a table had been positioned along one wall (see Figure 1). The tunnel floor from the outside edge of the table to the opposite wall was sectioned into six lanes, each lane measuring 76 cm in width (approximately one body width). These lanes were marked by placing small pieces of black tape on a 2-cm expansion strip that ran the width of the tunnel, through the center of the table. Experimental observers sat in a lounge area approximately 6.5 m from the table, from which subjects could be clearly observed as they were both approaching and passing the table.

Procedure. The experiment was conducted during the afternoon of 1 day and the morning of the next. No subjects were observed within 10 minutes of breaks between classes, due to the large numbers of people using the tunnel at these times. This restriction also prevented individuals who were in a particular hurry to go to (or away from) class from being used as subjects. Six volunteer undergraduate observers (three on each of the 2 days) sat unobtrusively in the lounge area across from the table. As people approached the table from the library, each observer selected a subject who met the criterion of being alone, made certain that none of the other observers was monitoring that same subject, and recorded the lane through which the subject walked as he or she passed the table. As soon as a recording had been made, the observer selected the next subject walking alone and unmonitored by the other observers. Each observer monitored the same number of subjects under each of the four experimental conditions. Prior testing had indicated greater than 95% interrater agreement as to which lanes subjects had used in passing the table.

On each of the 2 days, the conditions were arranged in a different random order, and approximately half the subjects in each condition were observed on each day of the study. In the two person-present conditions, a female undergraduate confederate sat on the chair behind the table. She made no attempt to solicit donations but sat silently and watched the activity in the tunnel, avoiding direct eye contact with subjects who were being monitored. In the no-person-present conditions, the chair was empty.

In the two donation conditions, a cardboard donation box (34 × 23 × 47 cm) was positioned on the table near the end closest to approaching subjects. It was covered on all four sides and on the top with posters from the donation agency (United Way). Each of these posters consisted of a white back-

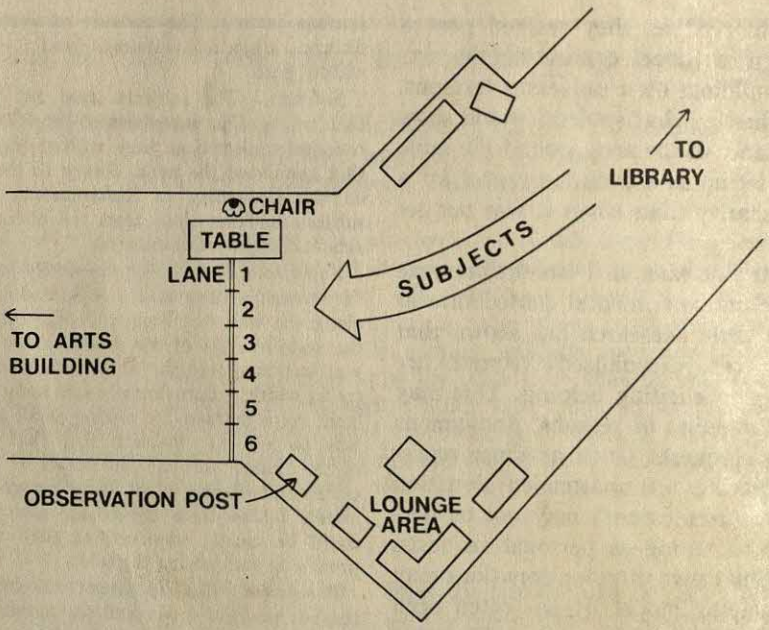

Figure 1. Experimental site.

ground with 2 cm of black lettering on the top and bottom and the agency's logo in orange in the center. The lettering on the top of each poster read "Thanks to you it's working," and on the bottom it read "United Way." In addition, a scaled-down version of the poster (17 × 25 cm) was placed behind the box so that it was clearly visible to people walking from the library. In the no-donation conditions, the table was bare.

Results and Discussion

Mean distances maintained from the table as subjects passed by are presented in Table 1.[1] Cochran's test for homogeneity of variance revealed significant differences among cell variances ($C = .366$, $p < .05$). Distance scores were therefore converted to reciprocals before being submitted to analysis of variance. Transformed scores appeared to be homogeneous ($C = .310$, *ns*).

Analysis of variance of the transformed data revealed a main effect for the donation factor, $F(1, 176) = 6.03$, $p < .025$. Subjects maintained a greater distance from the table when it displayed a poster and donation box than when no donation request was implied. A main effect was also obtained for the person factor, $F(1, 176) = 13.46$, $p < .001$, subjects maintaining a greater distance from the table when the female confederate was present than when no one was at the table. The Donation × Person interaction was not significant, $F(1, 176) = .40$, *ns*.

Only three subjects made donations, two in the person and one in the no-person condition. Analysis of variance of the distance measure excluding these subjects revealed the same patterns of significant differences.

These results suggest that people do actively avoid situations involving charitable donations. The results further indicate that personal appeals will produce more avoidance than anonymous appeals. It is unlikely that the presence of the confederate produced more avoidance because of the normative pressures implied or because the appeal was somehow stronger; her presence produced more avoidance in the nondonation conditions as well as in the donation conditions. This suggests that much of the avoidance may stem from the invasion of personal space that can occur when a personal appeal is made.

[1] Subjects never used Lanes 5 or 6 in walking to the arts building and only infrequently used Lane 4. This was most likely because the lanes with lower numbers represented the shortest path to the arts building.

Table 1
Distance Maintained from Table: Study 1

Donation factor	Person factor: Person present	Person factor: No person present
Donation sought	1.71	1.33
No donation sought	1.42	1.20

Note. Distances are in terms of 76-cm units.

Study 2

The second experiment was conducted to replicate the findings of Study 1 and further to examine differences between personal and impersonal appeals in evoking avoidance behavior.

Study 1 did not control for the effects of sex of subject or the nature of the charity involved. It is possible that differences in avoidance behavior were the result of having different proportions of males and females in each of the cells. It may also be possible that subjects' feelings about the particular charity involved may have produced a different pattern of avoidance than if another charity had been used. For these reasons, sex of subject was included as a factor in Study 2, and the appeal was made on behalf of the United Nations Children's Fund (UNICEF), a different charity from that used in Study 1.

It is often the case in appeals for donations that members of the disadvantaged group act as canvassers. While potential donors may be more sympathetic to handicapped canvassers, the research literature suggests that disabled individuals can also elicit greater avoidance. For example, Acton, Bentley, Matheson, & Stewart (Note 2) found that subjects avoided looking at a disabled person more than at a nondisabled person during the course of an interview. In a study by Kleck, Ono, and Hastorf (1966), subjects interacting with a handicapped individual terminated the interactions sooner than did subjects interacting with a nonhandicapped individual. In Study 2, subjects again walked by a table that did or did not display a donation box and at which a handicapped confederate, a nonhandicapped confederate, or no one was seated. It was hypothesized that greater avoidance would occur when the handicapped individual sat at the table, less avoidance would occur when the nonhandicapped person was at the table, and least avoidance would result when no one was seated at the table.

Method

Summary of design. The experimental design was a $2 \times 2 \times 3$ factorial. Male and female subjects (sex factor) were monitored as they walked past a table that was or was not set up as a center for donations (donation factor). Seated at the table was a handicapped person, a nonhandicapped person, or no one (person factor). Again, the dependent measure was the distance maintained by subjects as they walked past the table.

Subjects. The subjects were 462 people (51 males and 26 females in each of six experimental conditions) who were randomly selected as they walked from the library to the arts building as described in Study 1.

Experimental site. The site used was the same as in Study 1. The only change made was in the width of the lanes marked along the tunnel floor. The lanes had been reduced from 76 cm to 62 cm in width. This provided for finer distance discriminations with no apparent loss in interrater reliability.

Procedure. Subjects were observed during three sessions, in the morning and afternoon of one day and in the morning of the following day. Approximately the same number of subjects were observed in each of the three sessions. Two observers monitored subjects in the same manner as in Study 1. The experimental conditions included all six combinations of the donation factor and the person factor. These six conditions were arranged in a different random order for each of the three experimental sessions.

The three donation conditions were somewhat different from those in Study 1, since a different charity was being used. In these conditions a sign reading "Please donate to UNICEF" was hung from the end of the table facing oncoming traffic. A donation box ($18 \times 18 \times 23$ cm) was positioned on the table as in the first experiment. In the no-donation conditions, the table was bare.

In the handicapped-person conditions, a male confederate sat in a wheelchair near the end of the table that faced oncoming subjects. The wheelchair was backed against the wall and slanted toward the traffic at a 45° angle. Both the wheelchair and the donation sign were clearly visible to approaching subjects. In the nonhandicapped-person conditions, the confederate sat in an ordinary chair, positioned exactly as the wheelchair had been. In the no-person conditions, this chair was empty.

Table 2
Distance Maintained from Table: Study 2

Donation factor	Person factor		
	Handicapped	Nonhandicapped	No person
Donation sought	2.08_a	1.99_a	1.30_{bd}
No donation sought	1.66_b	1.44_{bc}	1.13_d

Note. Distances are in terms of 62-cm units. Means carrying different subscripts differ at the $p < .05$ level of significance.

Results

Analysis of variance of the distance measure revealed no main effects for sex of subjects and no interactions involving this variable. Consequently, the data were collapsed across sex and reanalyzed using a 2 × 3 (Donation × Person) analysis of variance. Mean distances are presented in Table 2. Cochran's test for homogeneity of variance again revealed significant differences among cell variances ($C = .232$, $p < .05$). Distance scores were therefore transformed as in Study 1 before being submitted to analysis of variance. Transforming the scores appeared to result in homogeneous cell variances ($C = .212$, *ns*).

Analysis of variance of the transformed data revealed a main effect for the donation factor, $F(1, 456) = 45.03$, $p < .0001$. As in the first experiment, subjects maintained a greater distance from the table when it was set up as a donation station than when it was not. A main effect was also obtained for the person factor, $F(2, 456) = 60.96$, $p < .0001$. Planned comparisons showed that the greatest distances were maintained from the table at which the handicapped person was seated, intermediate distances were maintained from the table at which the nonhandicapped person was seated, and least distances were maintained when no one was at the table, $t(456) = 2.17$, $p < .05$ for handicapped versus nonhandicapped means; $t(456) = 8.29$, $p < .001$ for nonhandicapped versus no-person means; $t(456) = 10.46$, $p < .001$ for handicapped versus no-person means.

Analysis of variance also yielded a marginal Donation × Person interaction, $F(2, 456) = 2.84$, $p < .06$. Multiple comparisons of the cell means (indicated in Table 2) show that while the donation and no-donation means did not differ when there was no person at the table, they did differ significantly when either a handicapped or a nonhandicapped confederate sat at the table.

Only a relatively small number of people donated money during the course of the experiment. Twelve people made donations, in all; 5 when the handicapped confederate was present, 6 when the nonhandicapped confederate was present, and only 1 when no one was at the table. Naturally, these people were recorded as passing the table in Lane 1. Prior analysis that excluded these subjects revealed the same patterns of significant differences.

General Discussion

These results provide support for the hypothesis that people will often avoid situations in which they are asked to give help. The main effects found in both studies for the donation factor suggest that the appeal itself, regardless of its impersonal or personal nature, elicits avoidance behavior. The main effects found for the person factor in both studies indicate that another element involved in producing avoidance on the part of potential donors may be the invasion of personal space that can occur when one is approached by an unfamiliar person seeking a donation. However, the Person × Donation interaction found in Study 2 suggests that there may be another important component operating in personal appeals for help. The fact that personal appeals (by a handicapped or nonhandicapped individual) yielded greater avoidance relative to the corresponding nondonation conditions than did nonpersonal appeals suggests that personal appeals represent more than an invasion of personal space. They may increase the strength of the appeal and thereby influence the donor's perceived choice as to whether or not to give. This would result in greater reactance and hence greater avoidance. Further support for this interpretation comes from the fact that the personal appeals, while

eliciting more avoidance, also produced more donations than the anonymous appeal.

Presumably, avoidance will be a function of the relative strength of the forces that motivate and inhibit helping. If those factors that motivate helping are much more powerful than those that inhibit helping, the individual will give help and suffer no conflict in doing so. If, on the other hand, the inhibiting factors are much stronger than the motivating factors, the individual will *not* help but, again, will suffer no conflict in doing so. Conflict (and hence avoidance) will be maximal when the forces that motivate helping and those that inhibit helping are equally strong.

These studies address an aspect of helping not often considered in helping research. Helping studies have typically been quite spare in the kinds of dependent variables they examine. Often the amount of help given is the only dependent variable considered. The results of the current research indicate that in looking only at amount of helping, investigators may be ignoring many aspects of the helping *situation*. A knowledge of the amount and kind of avoidance produced, for example, could aid greatly in understanding why people are often so reluctant to give help. Such considerations might also lead to more effective appeals, in which helping entails less conflict and aversion for the potential helper.

The Importance of Consistency of Modeling Behavior Upon Imitation: A Comparison of Single and Multiple Models

Peter A. Fehrenbach, David J. Miller, and Mark H. Thelen
University of Missouri—Columbia

The present study was designed to assess the differential effects of single versus multiple adult models on children's expression of preferences when the modeled preferences are either consistent or divergent. Second- and third-grade children were exposed to either a single model who made two choices per trial or to two models (multiple models) who made one choice each per trial. The modeled choices were either identical (consistent) or different (inconsistent) from each other on every trial of two four-option preference tasks. A single-response control condition was included, in which a single model made one choice per trial. As expected, children who observed multiple models whose choices were consistent (multiple–consistent) imitated more than any other group. Children who were exposed to two models whose choices differed from each other on every trial (multiple–inconsistent) showed little imitation of either model. An intermediate amount of imitation was observed for the single model conditions, with the single model who made two identical choices per trial (single–consistent) resulting in more imitation than the single model whose choices were inconsistent on each trial (single–inconsistent). The single–consistent group and the single-response control group did not differ in imitation, but the two inconsistent modeling groups showed significantly less imitation than the control group.

Research on the effects of modeling typically has been conducted within a methodological framework in which a subject observes the behavior of a single model. Yet in naturalistic settings, individuals often observe the responses of more than one person to a given situation. This phenomenon has been called multiple modeling and may involve similar or divergent responses on the part of the models (Bandura & Walters, 1963). The present study was designed to assess the differential effects of single versus multiple adult models on children's imitation of preferences when the modeled preferences are either consistent or divergent.

Previous research suggests that multiple models are more likely than a single model to facilitate maintenance of reductions in the fear of dogs in children (Bandura & Menlove, 1968). However, in that study the multiple modeling subjects viewed the models interacting with different dogs, whereas the single model interacted with only one dog. Thus, the number of observed models and the number of feared stimuli were confounded. With such a confound removed, greater reductions in snake avoidance (Kazdin, 1974) and larger increases in self-reported assertive social skills (Kazdin, 1975, 1976) have been reported when multiple covert modeling procedures rather than single covert modeling procedures were used.

Other research has examined the effects of live multiple modeling cues on children's standards of self-reward, sharing, and resistance to temptation. In support of the notion that consistently deviant modeling cues operate additively, Allen and Liebert (1969) found that exposure to two deviant adult models weakened children's adoption of previously learned standards of self-reward more than exposure to a single deviant model. Also, Liebert and Fernandez (1970) found that

nursery school boys were more likely to imitate specific norms for sharing when multiple models demonstrated the norm as compared with a single model.

In making a direct comparison of a single model with two models, Allen and Liebert (1969) and Liebert and Fernandez (1970) confounded the number of models with the number of exposures to the modeled behavior. In both studies the single model condition consisted of essentially one exposure to the deviant or generous model's behavior, whereas in the multiple modeling condition subjects observed twice the number of deviant or generous responses. The greater behavioral change observed following multiple modeling may have been simply a function of increased exposure to the deviant or generous behavior, regardless of the number of models.

Other support for the hypothesis that modeling cues operate additively comes from McMains and Liebert (1968), who have shown that children exposed successively to two models, one of whom behaved in accordance with rules (strict model) and the other in a deviant fashion (lenient model), showed more rule violation than children exposed to two strict models and less rule violation than children who observed two lenient models. Wolf (Note 1) obtained similar effects of multiple models upon children's resistance to temptation.

Two methodological considerations limit the generalizability of the findings of McMains and Liebert (1968) and Wolf (Note 1) with respect to the effects of discrepant multiple models upon imitation. First, in many situations in which multiple models demonstrate discrepant behaviors (e.g., in the expression of preferences or judgments), the observer has the option of not imitating either model in addition to the option of imitating one or more of the models. In the McMains and Liebert (1968) and Wolf (Note 1) studies, nonimitation was impossible to the extent that the subject's violation of the rule could be taken as indicating imitation of the lenient model and adherence to the rule as imitation of the strict model. Second, in both studies, the child's behavior was measured after the modeling manipulations and when the child was alone. Under conditions where a child must respond in the presence of models, it is more likely that the observer will anticipate the social consequences of imitating or not imitating. Thus, when two models are divergent in their behaviors, the observers may perceive imitation of one model as offensive to the other, nonimitated model. Given the option of nonimitation, such perceptions could result in lower levels of imitation of either model than would be predicted by the hypothesis that modeling cues operate additively.

Different kinds of social factors seem to be operating when an individual responds in the presence of a single model. In this case the specific characteristics and behavior of the single model are more important in determining imitation. For example, an adult model who demonstrates consistency in preferences is likely to be viewed as more certain and deserving of emulation than an adult who is inconsistent or vacillating in his or her preferences.

The present investigation differed methodologically from previous studies on multiple modeling in several ways. The experimental tasks involved the expression of preferences, rather than self-initiated standards of behavior, and were performed in the presence of the model(s). The number of exposures to modeled behavior was controlled by having the single model make two responses, the same number of responses that occurred in the multiple modeling conditions where two models responded once each. Finally, a 2×2 factorial design was employed with the number of models (single vs. multiple) and type of modeling (consistent vs. inconsistent responses) as the main factors. A single model – single response control group was also included.

It was expected that the effects of multiple modeling on imitation of preferences would depend upon whether the models were consistent or divergent with each other in their choices. When both models expressed the same preference, high levels of imitation were expected. When the models expressed preferences different from each other, very little imitation of either model was expected. An intermediate amount of imitation was pre-

dicted for single model subjects, the inconsistent – single modeling condition resulting in less imitation than a consistent model.

Method

Subjects

The subjects were 80 second- and third-grade children (40 female and 40 male) from a primarily middle-class public elementary school. The experimenter was a senior undergraduate male, and the models were two female undergraduates. The subject pool was counterbalanced across the four experimental conditions and one control condition with respect to sex, grade, seating position of the model(s), the order in which the models responded in the multiple modeling conditions, and the model confederate utilized in the single modeling conditions. Each of the five conditions contained 16 subjects.

Tasks and Materials

Two limited-option preference tasks were used in this study. The colors task involved 10 5 × 8 inch index cards with four 1-inch color squares attached horizontally across the cards. The color squares varied only slightly in shades of the same basic color on any given card.

The faces task consisted of 10 emotionally expressive faces, each mounted on a 5 × 8 inch index card. Below each face were typed four nonsense syllables, which were three-letter consonant-vowel-consonant trigrams with an associative value of less than 15% (Archer, 1960).

Procedure

The experimenter escorted the subject individually to the experimental room, and the model arrived shortly after the subject. In the multiple modeling conditions, the second model arrived shortly after the first model. The models were introduced to each other and to the experimenter in order to decrease suspicion on the part of the subject that the models knew each other or the experimenter. The subject and the models sat across a table from the experimenter, the subject being seated between the two models in the multiple modeling conditions. The experimenter then explained that he was seeking the assistance of students and teacher aides in deciding which colors to paint some classrooms.

In both of the single model conditions, the model and subject were told that each would have a chance to pick a color. In order to determine who went first, the experimenter drew their names from a box. The model's name was always selected first, and she was told that she could therefore go twice before the subject made a selection from the colors. Both model and subject were told that each choice they made could be the same or different from the previous choices.

The experimenter then administered 10 trials on the colors task. On each trial in the single–consistent condition, the model always pointed on her second chance to the *same* color square that she had selected on her first turn. In the single–inconsistent condition, the model always selected a *different* color square on her second turn. In all conditions the model's choices were randomly determined.

After 10 trials on the colors task, the experimenter told the subject and model that he was writing a children's book and needed their help in picking "crazy names" to go with faces. They were asked to pick the name they thought went with the face. Ten trials on the faces task were then administered. As on the colors task, the model in the single–consistent condition pointed to the same name twice. In the single–inconsistent condition the model picked two different names on each trial.

In both multiple modeling conditions, the models and subject were told that each would have a chance to pick colors. Again, the experimenter drew names from the box to determine the order to be followed in making their choices. The models' names were always drawn before the subject in a prearranged, counterbalanced order. The rest of the instructions for both tasks were essentially the same as in the single model conditions, except that both the models and subject were told that they could make one choice of colors (or names) per trial. On each trial in the multiple–consistent condition, the second model always expressed the same preference as the first model. In the multiple–inconsistent condition, the second model always selected a different color or name from the first model.

The order of responding in the single-response control condition was established in the same way as in the two single modeling groups. However, the model was instructed to go first and to make only one choice per trial.

Results

The number of trials on which the subject matched a model's choice on the color task and the faces task and the sum of the matched responses on colors plus faces were used as the main measures of imitation. In general, the results of the analyses of the separate tasks are consistent with those obtained when matched responses on the two tasks were summated. Therefore, unless otherwise indicated, only the results of colors plus faces will be reported. Preliminary analyses indicated no significant effects on any of the dependent measures with respect to model confederates, seating position of the model(s), or the order

in which the multiple models made their choices. Therefore, the data were pooled across these variables in subsequent analyses.

Table 1 presents the means and standard deviations of the number of matched responses on colors plus faces tasks for the five groups. Inspection of this table reveals that the predicted interaction of number of models and consistency of modeled responses was obtained. To test the reliability of this finding, a $2 \times 2 \times 2 \times 2$ analysis of variance was performed, the factors being number of models (single vs. multiple), type of modeling (consistent vs. inconsistent), grade of subject (second vs. third), and sex of subject. A significant main effect for number of models and type of modeling was obtained, but the predicted interaction of number of models and type of modeling was also highly significant, $F(1, 48) = 20.71$, $p < .001$.

Two-tailed t tests indicated that as predicted, more imitation occurred in the multiple–consistent group than in the single–consistent condition, $t(48) = 5.92$, $p < .001$. Also as predicted, the single–consistent condition resulted in more imitation than the single–inconsistent condition, $t(48) = 2.01$, $p < .05$. Finally, although the means are in the predicted direction, the mean for the single–inconsistent group was not significantly greater than the mean for multiple–inconsistent group.

In summary, multiple models who were consistent with each other in the expression of preferences more strongly influenced the children to imitate than a single model who made

Table 1
Means and Standard Deviations of the Total Number of Matched Responses on the Colors Plus Faces Tasks

Condition	No. of matched responses	
	M	*SD*
ultiple–consistent	10.56	4.93
ultiple–inconsistent	2.06	2.32
ngle–consistent	4.63	2.42
ngle–inconsistent	2.56	2.00
ngle-response control	4.00	2.03

two consistent choices. However, multiple models who showed divergent preferences were imitated very little. These predicted results were obtained despite the fact that the probability of obtaining matching responses by chance alone was higher in the inconsistent conditions, where two of the four options were modeled ($p = .50$), than in the consistent conditions, where chance imitation was only one out of four ($p = .25$). Imitation was significantly greater than chance in the multiple–consistent condition, $t(15) = 3.92$, $p < .01$, but significantly less imitation than that expected by chance alone was obtained in the multiple–inconsistent and single–inconsistent conditions, $t(15) = -13.67$, $p < .001$, and $t(15) = -14.89$, $p < .001$, respectively.

An unexpected three-way interaction of number of models, type of modeling, and sex of subject was obtained, $F(1, 48) = 4.02$, $p < .05$. Separate comparisons of males and females in all four experimental groups revealed that the only significant sex differences occurred in the multiple–consistent condition, where the female subjects imitated more than males, $t(48) = 4.50$, $p < .001$.

Finally, nonorthogonal planned comparisons of the single-response control condition with the four experimental groups were performed. The multiple–consistent condition evidenced more imitation than the control group, $t(75) = 6.28$, $p < .001$ (all t tests are two-tailed). The single–consistent group did not differ in imitation from the single-response control group. However, the multiple–inconsistent group ($M = 1.06$) imitated less than the control group ($M = 2.31$) on faces, $t(75) = -2.27$, $p < .05$; there was only a trend in the same direction on colors plus faces, $t(75) = -1.86$, $p < .10$. Similarly, subjects in the single–inconsistent condition ($M = 1.06$) imitated less than control subjects ($M = 2.31$) on faces, $t(75) = -2.02$, $p < .05$; a trend in the same direction was obtained for colors plus faces, $t(75) = -1.38$, $p < .20$.

In summary, under the present conditions it appears that exposure to a single model making two consistent responses does not increase imitation over that obtained after observing a single model responding once. The likelihood of imitation does increase, however,

when multiple models respond consistently with each other. While it thus appears that multiple models are required to increase imitation, imitation may be decreased by inconsistent modeling, regardless of the number of models. This is evident by the finding of equivalent reductions in imitation in both inconsistent groups relative to the single-response control group and the single–consistent group.

Discussion

The results provide support for the notion that observing multiple models can increase imitation of preferences in children significantly over that obtained after observing a single model. These results were obtained when the number of exposures to modeled behavior was equated in both the single and multiple model conditions. Previous studies comparing single and multiple modeling have failed to control for the number of exposures to modeled behavior. However, the results also strongly suggest that a greater degree of imitation with multiple models can only be expected when the multiple models present consistent behaviors to imitate. When multiple models appear to be in conflict or are otherwise divergent in their behavior, very little imitation of either model can be expected.

The finding of a dramatic attenuation of imitation in the multiple–inconsistent condition warrants some explanation. While much of the research on imitation has emphasized the unidirectional impact of modeling on the subsequent behavior of a naive subject, more recent studies have considered the reciprocal-influence process involved in the ongoing model–imitator interaction. It has been found, for example, that being imitated is reinforcing to the model and leads to reciprocal imitation and to increased attraction on the part of the model toward the imitator (Thelen, Dollinger, & Roberts, 1975). Given that the effects of being imitated are often positive, it is likely that children who observed two high-status adults (supposedly teacher's aides) expressing different preferences were conflicted regarding which one to imitate. Children in the second and third grades may realize the possible negative social consequences (e.g., lowered attractiveness) of choosing to imitate or conform with one adult rather than another. Given the option not to imitate, as was the case in this study, the children may have chosen to avoid the conflict by imitating neither model.

A different explanation is suggested when one notes that, although they were in the predicted direction, the differences between the single–inconsistent and multiple–inconsistent conditions were not significant. These results, considered in conjunction with the finding that both inconsistent conditions resulted in less imitation than the two consistent conditions, indicate that the crucial variable accounting for the low levels of imitation in the multiple–inconsistent condition may be the inconsistency of modeling cues per se, rather than social interaction variables associated with the number of models.

A third explanation for the low levels of imitation in the multiple–inconsistent condition involves the possibility that the subjects were actually imitating the nonimitative (divergent) behavior of the second model. The second model was thus demonstrating oppositional behavior toward the first model and giving tacit acknowledgment that the child could similarly make a choice different from that of the first model. Brehm (1977) found that when one adult's attempt to influence children's choice preferences was followed by a second adult's suggestion that they should choose whatever they wanted, first graders (but not fifth graders) acted in opposition to the first adult. Perhaps simply observing conflict in preferences among high-status adults disposes a child not to imitate either adult's choices. The potential effects upon socialization resulting from a child's receiving conflicting modeling cues from such significant adults as parents remains to be determined in research conducted in more naturalistic settings than those employed in the present study.

With respect to the single model conditions, it appears that doubling the number of exposures to modeled choices in the single–consistent conditions did not result in more imitation than the single model - single-response control condition. However, when the single

nodel made two divergent choices, the chil-lren were less likely to imitate either choice han when the model made the same choice wice. The difference in imitation between hese two single model groups may have been n part a function of the lowered esteem in vhich the inconsistent model was held relative o the consistent model. Or, as mentioned arlier, the inconsistency of modeled informa-ion (cues) may result in reduced imitation ndependent of social factors.

This study presents strong support for the ypothesis that multiple models are more ffective in producing imitative behavior than single model. This finding is only supported, owever, when the models behave consistently vith each other. Oppositional behavior or low evels of imitation or compliance are likely to esult when two models conflict in their be-avior or when a single model behaves incon-istently. Further research conducted in more aturalistic settings is necessary to determine vhether inconsistency in modeling cues pre-ented by either single or multiple models ignificantly affects socialization. For example, f parents in marital conflict provide divergent nodeling cues, what effect might this have on heir children's behavior?

Self-Serving Attributional Biases: Perceptual or Response Distortions?

Gifford Weary
Ohio State University

The present article examines Miller's analysis of what constitutes a self-serving attributional bias. It is argued that his delineation of different types of self-serving attributions is not supported by the empirical evidence collected to date and that what previous authors (e.g., Miller & Ross) have viewed as a perceptual bias in the causal inference process may be better seen as a response bias or as a strategic self-presentation designed to maximize public esteem.

In Miller's (1978) recent reply to my re-examination of the notion of self-serving biases in the causal inference process (Bradley, 1978),* he discusses the merit of my broadened self-serving bias formulation and addresses the important issue of what constitutes a self-serving attribution. While an examination of this latter issue is long overdue, I will argue in the present article that the analysis presented by Miller serves only to obfuscate issues in an already confusing area of inquiry. Moreover, I will contend that in his reply, Miller (a) incompletely summarized my formulation of self-serving attributional biases and (b) failed to address important criticisms raised in my examination of Miller and Ross's (1975) information-processing analysis of data that have been interpreted as reflecting motivational biases.

In my review (Bradley, 1978) of the empirical evidence relevant to the proposition that self-serving biases modify attributions of causality, I presented a broadened formulation to account for seemingly counterdefensive attributions (i.e., attributions indicating greater acceptance of responsibility by the attributor for negative than for positive outcomes attendant upon his/her behavior). Specifically, I suggested that self-serving attributions may be viewed as public self-presentations designed to maximize public esteem and that *under certain conditions* such esteem needs may be best served by accepting responsibility for negative outcomes.

While Miller (1978) feels this broadened formulation "has the virtue of parsimony" (p. 1221), he also states that it "seems to vitiate the virtue of parsimony by being over-inclusive and allowing *any* asymmetrical attributions for success and failure to be interpreted as being self-serving in nature" (p. 1221). It is important to note, however, that certain major *conditions* under which one would expect esteem motives to lead to defensive versus counterdefensive attributions were specified in my earlier article. It was pointed out that in all of the studies that have offered support for counterdefensive attributional processes, there has existed the opportunity to compare simultaneously the subject's self-attribution for his or her own task performance with his or her subsequent behavior on a similar task or with another's causal attribution for the subject's outcome. I suggested (1978, pp. 64–66) that the probable *simultaneous comparison* of and *potential inconsistency* between one's description of causality and (a) one's subsequent behavior and/or (b) another's description of causality for one's performance outcomes may prevent an individual from taking too much credit fo

The author thanks John H. Harvey for his helpful comments on an earlier draft of this paper.

success or denying blame for failure. In view of this reasoning, I contend that the broadened formulation is not "overinclusive" and is not invulnerable to disconfirmation.

In an attempt to define a self-serving attribution, Miller (1978) suggests that attributions for positive and negative outcomes can represent either distortions in perception of causality or distortions in descriptions of causality. That is, "they can serve to protect or enhance how the person perceives himself or herself" or "they can serve to protect or enhance how *others* perceive the person" (p. 1221). Moreover, Miller argues that my analysis of self-serving attributional phenomena has obscured two distinct psychological processes, because I use the term *self-serving* to refer to attributions that serve one's public image, whereas previous authors have used this term to refer to attributions that serve one's private image.

There are several problems associated with this statement. First, as Miller (1978) himself admits, there is little evidence to support the proposition that "we are prone to alter our *perception* of causality so as to protect or enhance our self-esteem" (p. 1222). In most of the studies reviewed by Miller and Ross (1975) and myself (Bradley, 1978), subjects' performances and causal interpretations were public in nature; consequently, subjects' causal ascriptions for their positive and negative outcomes likely reflected "distortion in descriptions or self-presentations, not perceptions" (Miller, 1978, p. 1222).[1] Second, the preceding statement should not be taken to imply that private self-esteem needs are not influenced by distortions in descriptions of causality. For example, if the self-serving bias effect is mediated by a desire to maintain or gain a positive public image, then positive evaluations from others may serve to enhance the esteem one feels for oneself; conversely, negative evaluations from others may threaten the individual's positive, private self-image. Based upon the empirical evidence collected to date, then, what previous authors (e.g., Miller & Ross, 1975) have viewed as a perceptual bias in the causal inference process may be better viewed as a response bias or strategic self-presentation designed to maximize public esteem (Bradley, 1978) and, secondarily, private self-esteem.[2]

In their 1975 review, Miller and Ross proposed that the results of many of the studies often cited as support for self-serving attributional biases could readily be "interpreted in information-processing terms" (p. 224). Specifically, they contended that the observed tendency for individuals to accept greater responsibility for positive than for negative outcomes may occur for any or all of several reasons: (a) Individuals intend and expect success more than failure and are more likely to make self-ascriptions for expected than for unexpected outcomes, (b) perceived covariation between response and outcome may be more apparent for individuals experiencing a pattern of increasing success than for individuals experiencing constant failure, and (c) people erroneously base their judgments of the contingency between response and outcome in terms of the occurrence of the desired outcome (i.e., success) rather than any actual degree of contingency.

In my examination of the explanatory strength of these alternative interpretations of findings offered as evidence for self-serving attributional biases, I concluded that they

---

[1] The major issue underlying Miller's differentiation of two types of self-serving attributions involves the *locus* of distortion in the causal inference process (i.e., a perceptual vs. a response bias). However, I would argue that (a) there are probably multiple points of bias in the attribution process, from input to output, and (b) present evidence does not allow us to determine the precise point at which bias or defensiveness may be occurring. At this point in time, a more pertinent empirical question would seem to be how and under which conditions self-serving motivations influence attributions of causality.

[2] Miller suggests that securing behavioral measures might help future researchers determine whether individuals distort causal ascriptions for their positive and negative outcomes in order to serve their public or their private images. Since private self-esteem needs might be influenced by public self-presentations, it is not clear that behavioral measures would help determine whether the self-serving bias effect represents distortions in descriptions or perceptions. Moreover, it seems reasonable to argue that written or verbal measures of causal responsibility are in fact behavioral measures and that individuals may infer their private self-attributions from their public, behavioral statements of causality (cf. Bem, 1972).

suffer from conceptual incompleteness and a lack of parsimony. It is indeed unfortunate that Miller chose not to use his recent reply to my 1978 review as a forum for addressing these criticisms; while many of Miller and Ross's (1975) points are meritorious and deserve *direct* investigation, I suspect such experimentation will not be forthcoming until the alternative interpretations proposed by these authors receive considerable theoretical clarification.

In conclusion, it is contended that the validity and explanatory power of Miller and Ross's (1975) information-processing analysis of data presumably reflecting motivational biases in the causal inference process remains undetermined. In addition, it is concluded that the empirical evidence related to the notion of self-serving biases in causal attributions is most consistent with a self-presentation formulation holding that individuals alter their descriptions of causality so as to enhance or protect others' perceptions of them.

The Bias Phenomenon in Attitude Attribution: Actor and Observer Perspectives

Arthur G. Miller, Robert Baer, and Peter Schonberg
Miami University (Ohio)

Extensive research in attitude attribution has shown that observers infer correspondent attitudes from behavior that is externally constrained. The present study concerned (a) the degree to which actors anticipate observers' manifestation of this bias, (b) the effect of presenting constraint information directly from the actor as compared to the experimenter's instructions, and (c) the relationship between constraint experienced by the actor and the persuasiveness of essays produced under different constraint levels. Essay writers clearly predicted that observers would infer correspondent attitudes even when the position had been randomly assigned to the writer. This was true, although to a diminished extent, when the writer was under genuinely high constraint. When actors expected observers to have precise information regarding their actual constraint, however, they anticipated that observers would recognize the attributional implications of such information. Data from observers corroborated the actors' predictions. When observers were not given this information, their attributions were based solely on essay content and indicated no recognition of the different freedom levels experienced by the essay writers. Essays written under different constraint levels were judged by observers to be generally of similar and fairly respectable persuasiveness. It is suggested that the bias phenomenon may be a consequence of presenting observers with essays more persuasive than they expect from a writer who in fact disagrees with the assignment.

An individual's prediction of the attribution that others will make to him or her is an issue of practical as well as conceptual interest. Accurate predictions should enhance effectiveness in managing the impression one makes upon others. Conflicts could be eased by anticipating how others will view the causes of one's actions. Research attention has focused recently on attributional bias, in particular the tendency to overestimate the importance of personal or dispositional determinants relative to situational influence—what Ross (1977) has termed the "fundamental attribution error," which was a central concept in the article by Jones and Nisbett (1971). The present study was primarily concerned with three issues. The first was the degree to which actors anticipate or predict that observers of their behavior will manifest this particular bias. The second related to the source of constraint information—the effect of presenting constraint information *directly* from the actor and determining the impact of this kind of stimulus upon observers' attributions as well as upon actors' predictions of observer judgments. A final concern was the relationship between the amount of constraint experienced by the actor and the quality of the behavior produced under different constraint levels.

The procedure was a variation of a paradigm used by Jones and Harris (1967), in which subjects were told that a target person had written an essay under choice or no-choice instructions. Perhaps the most celebrated

finding of that study was the observation that subjects attributed attitudes in line with the essay content or direction (pro or anti) even when the position had been assigned to the writer. This finding has been reported in many experiments and is widely regarded as observer bias in the direction of personal causality (Jones, 1976, 1979; Jones & McGillis, 1976; Miller, 1974, 1976; Monson & Snyder, 1977; Ross, 1977; Snyder & Jones, 1974).

In the first part of the present experiment, actors were asked to predict the judgments of observers in the attitude attribution paradigm. Subjects were asked to write essays on affirmative action; they were either given a choice of position or were assigned to write in the *anti* or *pro* direction. After writing their essays, they were asked to predict the average attitude attribution that observers would make after reading the essays and after being informed of the instruction condition. Would actors predict attributions according to the model of correspondent inference theory? This would be shown by predicting correspondent inferences under the choice condition and predicting a normative or base-rate attitude, unrelated to essay directionality, in the assign conditions (Jones & McGillis, 1976). Actors should thus expect observers to feel confident that the essay represented the actor's true opinion in the choice condition but should expect observers to be in a very real dilemma in the no-choice or assign conditions and to make an attribution that would be the "best guess" under these circumstances.

Actors have an advantage over observers in being *explicitly* aware of the randomness of their essay assignment, their precise constraint in the actual writing of the essay, and their personal opinion on the essay topic. With these insights, actors could be expected to predict the discounting of their own behavior in the assign conditions. Conceptually, the necessary information (for example, randomness of assignment) is more salient to actors than to observers. Actors would therefore have at least the option of predicting the discounting strategy—a pattern dictated by attribution theory but one that observers do not appear inclined to endorse. Of particular interest were the predictions of actors who were asked to write essays contrary to their true opinion. Would these genuinely constrained actors expect observers to attach little informational value to their essay, or would they expect observers to base attributions upon the content of their essay? Perhaps the more likely outcome, given the available research data from observer subjects, is that actors, constrained or not, would predict correspondent inferences under the no-choice instruction. This latter outcome would suggest that the bias effect in attitude attribution not only results from the observer's lack of precise information regarding constraint but reflects a more constructive, intuitive strategy that subjects bring to their task of estimating attitudes from essays.

A second issue in the present study was the source of information concerning the actor's constraint. Jones and Harris (1967) and others have demonstrated bias by showing that perceivers appear to acknowledge neither the randomness of the writer's essay assignment in the no-choice conditions nor—a result of that randomness—the low informational or diagnostic value of the essay itself. There is a certain vagueness or abstractness to the no-choice instruction, however, in that it constitutes the *experimenter's* designation of the actor's situation but provides no explicit information concerning the *actor's* reaction to the essay assignment. In actual social interaction, the actor's personalized definition of the situation might be available to the observer. One might imagine a disgruntled writer muttering, "Oh, what luck, I would have to get *that* position—can I switch?" Would observers discount this type of information about constraint, coming directly from the actor? Would actors expect them to discount it? This issue was examined by comparing the impact of constraint information presented in the traditional, externally designated manner with information based upon the actor's own definition of the situation. It was expected that information concerning the actor's actual constraint would have a marked influence upon attributions of attitude, as well as predicted attributions, based on the essay. Specifically, indications of high constraint from the actor were expected to result in a discounting of the behavior.

A final concern was the persuasiveness of the essays produced in the assign conditions. Two relationships were examined. The first concerned the correlation between observers' attributions of attitude and their rating of the persuasiveness of the essay. The second concerned the degree to which essays composed under different constraint levels were judged as more or less persuasive. Data on these matters were considered as they might help explain the tendency for attributions to be associated with essay content in the no-choice conditions.

Method

Overview

In the first phase of the experiment, subjects filled out an attitude inventory, including an item that dealt with affirmative action. They were next asked to write a short essay and were either allowed to choose a position to defend or were assigned the pro or the anti position on the issue of affirmative action. In one condition, subjects were asked to rate their degree of freedom after having written their essay and to note this judgment at the bottom of the essay. In another condition, subjects were not immediately asked for this judgment. All subjects then estimated the average attribution that would be made by a group of observers who would read their essay and would judge the true attitude of the writer. Subjects were told that the readers would be aware of their condition (choice or assign). The subjects who rated their freedom after writing their essays were informed that observers would also have access to this rating. In a second phase of the research, subjects (observers) were given sets of essays written under varying constraint levels in the earlier part of the experiment. These subjects, who either were or were not shown the writer's freedom rating, were asked to estimate the writer's personal attitude on the issue of affirmative action and to indicate their opinion of the essay's persuasiveness. Subjects were then debriefed.

Subjects

In the essay-writing part of the experiment, the subjects were 276 undergraduates participating in research as a course requirement. Ninety subjects participated in the observer phase of the experiment. Subjects were seated at individual desks. Instructions were in written form, and subjects were seen in small groups (10 to 25). Subjects with procedural questions were aided individually by the experimenter.

Procedure

Actor predictions of observer attributions. The introduction to the experiment explained that it dealt with attitudes and the perception of beliefs. Subjects were informed that after filling out a short attitude inventory, they would be asked to write a short essay on one of the items and to fill out a questionnaire dealing with the essay that they had written. The key item on the 10-item attitude survey read as follows: "Women and other minorities should be given preference in job markets and other places where they are under-represented, assuming that they are qualified." Responses were made on a 10-point scale (1 = extremely disagree, 10 = extremely agree). In the second part of the experiment, described as a debate simulation, subjects were asked to consider the statement on affirmative action, as worded above, and to write a short, convincing essay in approximately 20 minutes. Subjects were randomly assigned to one of three categories listed at the top of the sheet upon which the essay was to be written. For each subject one category was checked in red: (a) choice of position, (b) assign pro, or (c) assign anti.

After writing their essays, subjects were randomly placed in one of two conditions. In one condition, to be termed *observer informed,* subjects were asked to rate the degree of choice or freedom they had while writing their essay. The definition of the low end of the scale (1 = no choice or freedom) was "as if you had copied the essay verbatim from another source." The high end (10 = complete choice and freedom) was defined as "indicating the completely free expression of your beliefs." This rating was located near the bottom of the $8\frac{1}{2} \times 14$ inch sheet upon which the essay had been written. In the other condition, to be termed *observer not informed,* subjects were not asked to make this freedom rating. All essays were collected. At this point, subjects were not aware of the specific questions that would follow.

Subjects then received questionnaires. The first item asked them to estimate the average attribution of a group of observers asked to read their essay and to guess their true opinion on affirmative action (1 = strongly against, 10 = strongly in favor). Subjects were informed that these observers would be shown the essay sheet and would be aware of the essay instructions. Subjects in the observer-informed condition, who had rated their freedom upon completion of their essay, were also told that observers would have access to this rating. After estimating the observers' attributions of attitude, subjects filled out several filler items on the two-page questionnaire. For subjects in the observer-not-informed condition, the freedom rating was included as the final item on the second page. The timing of the freedom rating and its mention (or omission) when predictions of observers' attributions were requested thus differentiated the observer-informed and observer-not-informed conditions. The design of this part of the experiment was a 3×2 factorial (Choice,

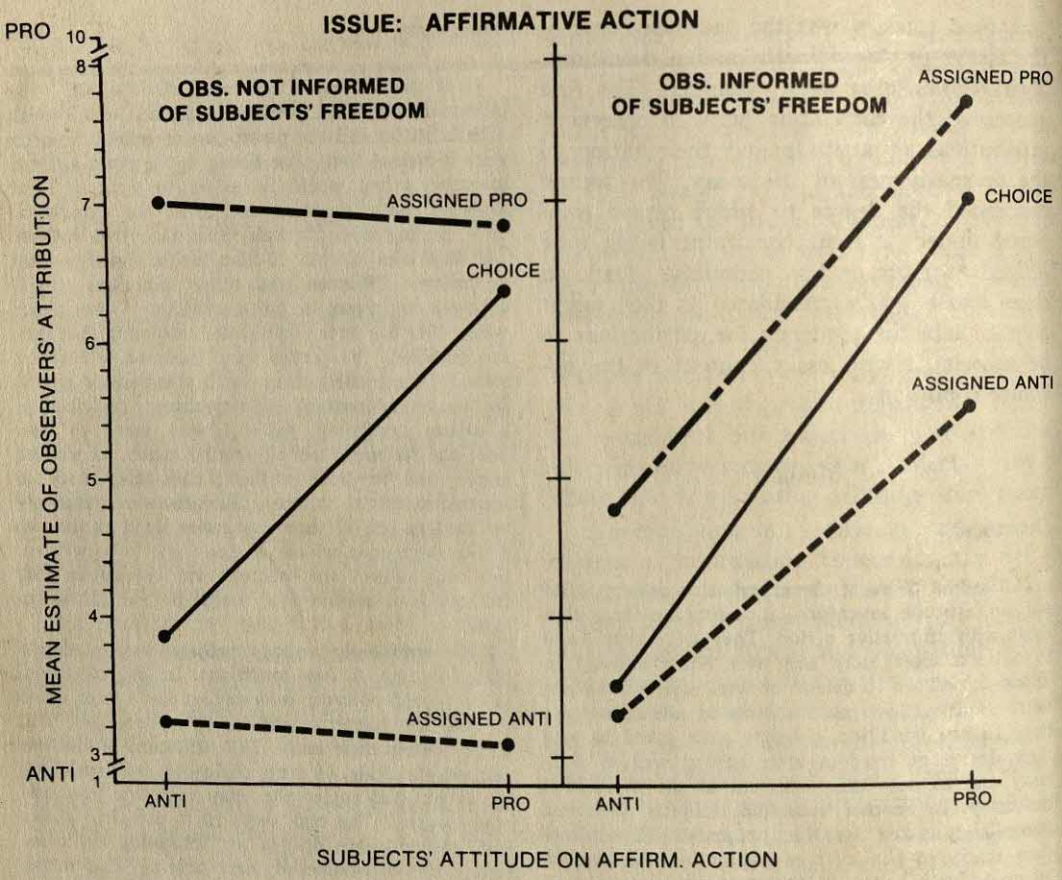

Figure 1. Mean estimate of observers' attributions as a function of writer's attitude, essay condition, and instruction regarding informing observers of writer's freedom. (Obs. = observer.)

Assign Pro, Assign Anti × Observer Informed/Not Informed).

Observer data. Ninety essays produced in the assign-pro ($n = 45$) and assign-anti ($n = 45$) conditions of *observer informed* were selected as stimuli for this phase of the experiment. The fact that the writer's freedom rating was located below the essay in this condition facilitated the presentation or omission of this information as the independent variable manipulation.[1] Ten copies of each of the 90 essays were made, with the writer's freedom rating masked on half. The essays were divided into nine sets, each set containing five assign-pro and five assign-anti essays written by actors who varied in their personal belief on affirmative action. Ten subjects were assigned to each set of essays, five subjects being given copies that included the freedom rating and five being given copies (of the same essays) that masked out the freedom rating. Subjects were asked to read each essay and make two judgments: an estimation of the writer's true attitude on affirmative action (1–10 scale) and an evaluation of the essay's persuasiveness (1 = very low, 10 = very high). Mean attitude attributions and persuasiveness ratings were then computed for each essay based on the judgments of subjects who were ($n = 5$) and were not ($n = 5$) shown the writer's freedom rating.

[1] The use of essays from the observer-informed condition was based strictly on the convenience of having the freedom rating located below the essays. There are no indications that the essays produced in this condition differed systematically from those in the observer-not-informed condition. The mean freedom ratings in the observer-informed conditions (assign pro = 5.17, assign anti = 5.84) did not differ significantly from those in the observer-not-informed conditions (assign pro = 4.89, assign anti = 5.50). In all conditions, subjects who were assigned a position counter to their personal belief reported less freedom than those assigned a position congruent with their belief. Correlations between own attitude and rated freedom for subjects in the observer-informed conditions were: assign pro—$r = .66$, assign anti—$r = -.52$; for subjects in the observer-not-informed conditions; assign pro—$r = .49$; assign anti—$r = -.41$.

Results

Actors' Estimates of Observers' Attributions

The subjects (actors) were first divided into two groups based on their attitude toward affirmative action, obtained in the original attitude inventory. Subjects who checked Responses 1–5 were categorized as *anti*; those checking 6–10 were categorized as *pro*. Subjects' predictions of observers' attributions were submitted to a $3 \times 2 \times 2$ analysis of variance, the independent variables consisting of the writer's essay condition (choice, assign pro, or assign anti), the writer's true opinion (anti or pro), and whether the writer did or did not expect the observer to have access to the writer's freedom rating (observer not informed or observer informed). Mean predictions of observer attributions are shown in Figure 1.

Two main effects achieved significance. Subjects assigned to write a pro essay predicted more pro affirmative action attributions than subjects in the choice condition, with subjects assigned to write an anti essay predicting the most anti attitude attributions ($M_{pro} = 6.39$, $M_{ch} = 5.17$, $M_{anti} = 3.68$), $F(2, 264) = 35.61$, $p < .01$. Subjects who were in fact pro affirmative action predicted more pro attributions than did subjects who were anti affirmative action ($M_{pro} = 6.04$, $M_{anti} = 4.18$), $F(1, 264) = 43.14$, $p < .01$. In terms of the central questions of this research, however, the data are best understood in terms of the Observer Not Informed/Observer Informed × Writer's Attitude interaction, $F(1, 264) = 15.05$, $p < .01$.

Consider the left panel for the observer-not-informed results. Subjects writing essays under the choice conditions predicted that observers would make correspondent attributions. Indeed, subjects under choice conditions invariably do choose to write in defense of their own attitude. However, subjects in the assign-pro and assign-anti conditions anticipated that observers would base their attributions solely on the essay itself. The subject's own attitude bears no relationship to the attribution the subject expected observers to make. This is a clear instance of the prediction of the "fundamental attribution error."

The right-hand panel shows the results for the observer-informed conditions. The result for the choice conditions is very similar to the observer-not-informed case, with subjects predicting correspondent inference. However, subjects in the two assign conditions clearly anticipate that observers will use the freedom rating information. The subjects' own attitudes thus bear a very strong relationship to the attributions they expect informed observers to make. There is still an effect of the particular assignment, however, in the observer-informed condition. Within the writer-anti and writer-pro conditions, the difference between the assign-pro and assign-anti means is significant at the .05 level. However, neither mean is significantly different from the choice-condition mean. There is, in summary, a strong demonstration of actors' predicting that observers will attribute attitudes on the basis of essay direction. If they expect observers to be informed of their actual constraint level, however, there is a marked modification in actors' predicted attributions, with writers expecting their true opinions to "come through" no matter what their particular assignment.

Also of interest is the relationship between the actor's self-rated freedom in the essay task and his or her prediction of observer attributions. For this analysis, only the responses from subjects in the two assign conditions were considered. Subjects were divided into three freedom categories based on their responses to the 10-point scale (1–3 = low; 4–7 = medium; 8–10 = high). Predictions of observer attributions were submitted to a $3 \times 2 \times 2$ analysis of variance (Freedom Level × Assign Pro/Anti × Observer Informed/Not Informed). Mean estimates of observer attributions are shown in Figure 2.

Subjects assigned to write pro essays estimated that observers' attributions would, in general, be more pro affirmative action than did subjects assigned to write anti essays, $F(1, 165) = 110.70$, $p < .01$. Within the pro and anti conditions, as self-rated freedom increased, subjects indicated that they expected observers' attributions to be more extreme in

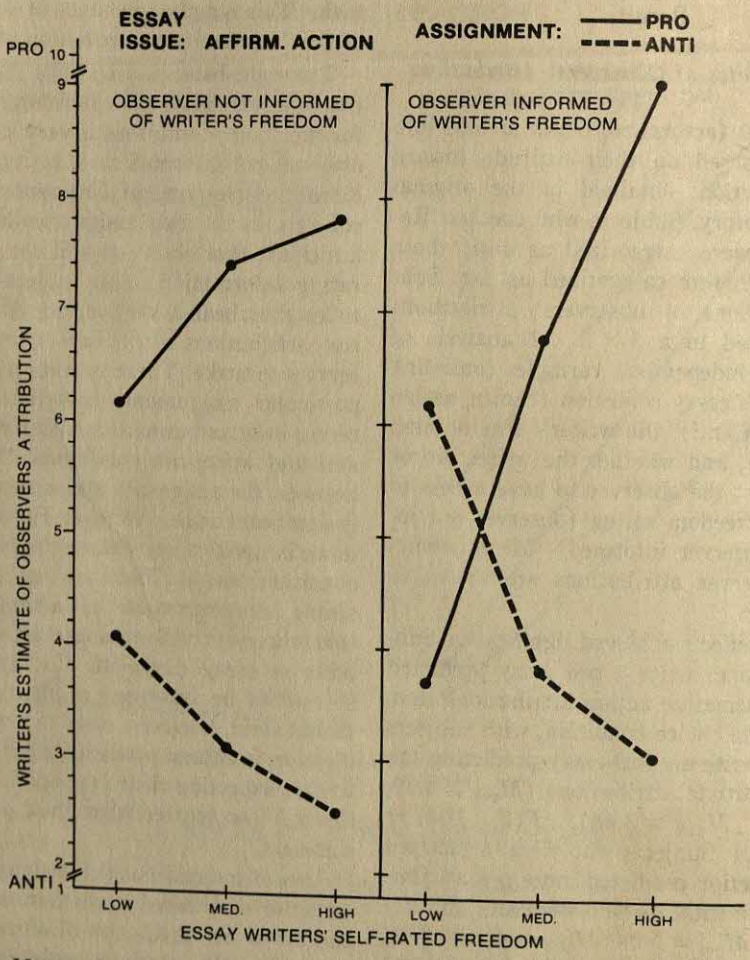

Figure 2. Mean estimate of observers' attitude attributions as a function of writer's freedom, essay condition, and instruction regarding informing observers of writer's freedom (choice condition omitted). (Affirm. = affirmative.)

the direction of their essays, for the Freedom × Condition interaction, $F(2, 165) = 34.42$, $p < .01$. Central to the issue addressed in this research, however, is the three-way Observer × Freedom × Condition interaction, $F(2, 165) = 7.44$, $p < .01$. When essay writers presumed freedom knowledge on the part of the observers (see the right panel of Figure 2), they clearly expected observers to use this information in an appropriate way. Thus, for writers who were under genuine constraint (low freedom), predicted attributions did not reflect their essay assignment condition but were in fact in the direction opposite to that condition. When essay writers did not expect observers to know their freedom ratings, they expected observers to make attributions in line with essay content (see the left panel of Figure 2). There is a clear suggestion, even in the observer-not-informed condition, that subjects experiencing less freedom expected observers to make less extreme attributions. However, even in the low-freedom condition, the assign-pro (6.16) and assign-anti (4.07) means are significantly different ($p < .05$).[2]

[2] To assess the reliability of this result, a replication of the observer-not-informed condition was conducted using a different attitude issue (allowing

From both views of the data (Figures 1 and 2), actors expect observers to base their attributions substantially on the content of the essay, provided that observers are not informed of the actor's actual freedom in the essay task. If actors do expect observers to be given this information, their predicted attributions assume a much different pattern, one that is closely and logically related to the writer's actual attitude and constraint level.

Observer Data

The mean attribution and persuasiveness judgments, which had been computed for each of 90 essays, were first divided into three categories based on the actual freedom ratings given by the writers of the essays (1–3 = low; 4-7 = medium; 8–10 = high). These means were then submitted to a 2 × 3 × 2 (Assign Pro/Anti × Freedom Category × Observer Informed/Not Informed) analysis of variance; means for these analyses are shown in Figure 3.[3]

Ratings of essay persuasiveness were generally similar, with an indication of a somewhat lower quality essay in the low-freedom, assign-anti condition. A Direction × Freedom Category interaction, $F(2, 168) = 4.33$, $p < .05$, indicated that persuasiveness ratings were similar in the three categories of assign pro (low = 5.85, medium = 5.81, high = 5.52), but were somewhat lower for assign-anti essays written with less freedom (low = 4.71, medium = 5.93, high = 6.03).

The attribution data, shown in the lower panels of Figure 3, indicate significant effects for essay direction, $F(1, 168) = 137.98$, $p < .01$, and the Direction × Freedom Category Interaction, $F(2, 168) = 16.58$, $p < .01$. Attitude attributions thus were more positive in the assign-pro than in the assign-anti conditions and were increasingly correspondent with essay directionality under conditions of higher freedom. The latter result, however, was unique to the observer-informed condition. The significant Direction × Freedom Category × Observer Informed/Not Informed interaction, $F(2, 168) = 9.73$, $p < .01$, indicates that freedom category had no influence on attitude attributions in the observer-not-informed conditions, whereas the impact of this information was very clear in the observer-informed condition. Data in the left panel indicate that attitude attributions were based on the content of the essays and reveal no recognition on the part of observers of the wide array of freedom or constraint levels actually experienced by the writers of these essays. The fact that the attributions are similar at each freedom category also suggests that the essays were perceived as similar in persuasiveness across freedom categories.[4] Data in the right panel, however, suggest that observers utilized the freedom ratings as a distinctive clue to the writer's personal attitude, with essay content being totally discounted at the low-freedom level.

Correlations among various judgment items are shown in Table 1. Without the freedom information, observers' attributions of attitude did not relate meaningfully to judgments from the writers (i.e., their real attitude, rated freedom, and predicted attributions). Subjects in the observer-informed conditions, however, attributed attitudes that related substantially and logically to writer judgments. Correlations

undergraduates to own and drive cars on campus). Essay directionality was, as expected, a strong determinant of predicted attributions, $F(1, 77) = 25.85$, $p < .0001$. A Freedom Level × Essay Direction interaction again characterized the data, $F(1, 77) = 4.18$, $p < .05$, with writers under low freedom predicting less correspondent attitudes (assign pro = 6.09, assign anti = 4.68) than writers under high freedom (assign pro = 7.06, assign anti = 3.84).

[3] Note that the same essays constituted the stimuli for the judgments in both the left and right panels of Figure 3. Judgments in the right-hand panels were obtained from subjects having access to the writer's freedom rating; data in the left-hand panels were obtained from subjects not given this information.

[4] If essays written under less freedom were lower in persuasiveness, attributions could reflect this diminution in strength. It would then not be possible to interpret less correspondent attributions as a pure reflection of the observer's knowledge of low freedom ratings per se, in that similarly less extreme attributions would be expected to accompany weaker essays. However, the persuasiveness ratings, as well as the attributions of attitude in the observer-not-informed conditions, strongly suggest that observers were not responding to systematic differences in essay persuasiveness at the various freedom levels.

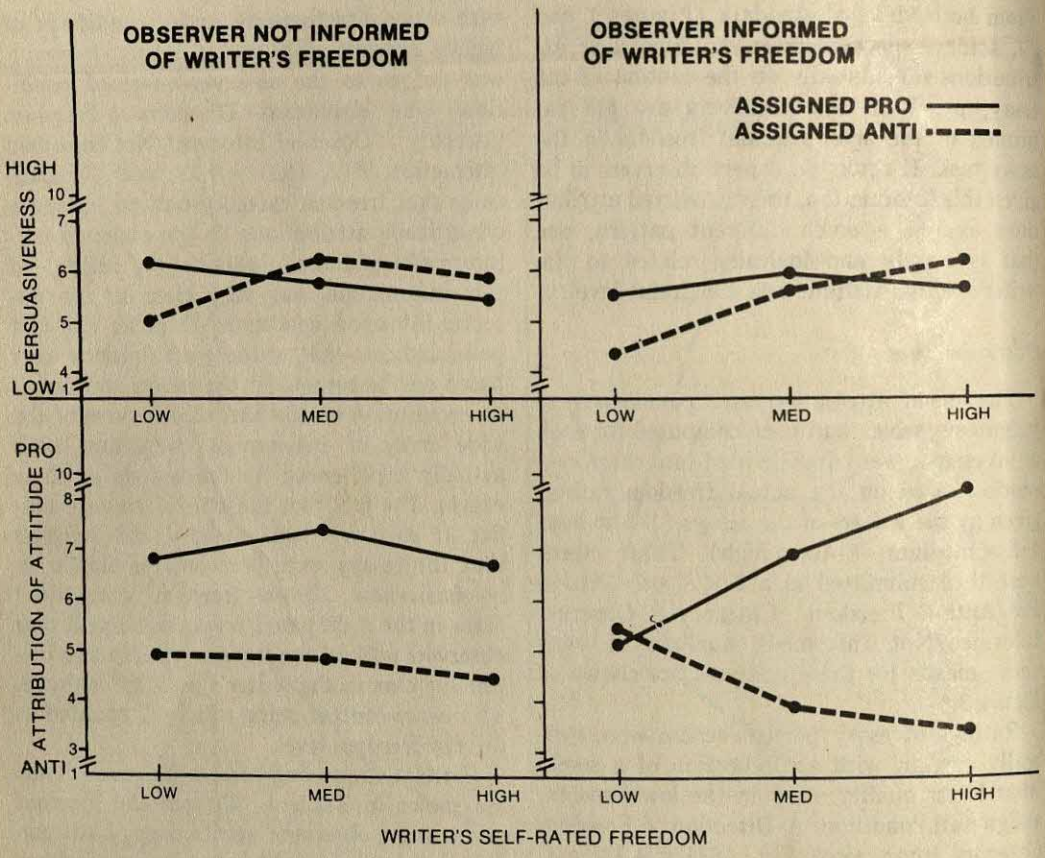

Figure 3. Mean persuasiveness ratings and attitude attributions for essays written at three freedom levels by observers who are or are not informed of the writer's freedom rating.

involving persuasiveness judgments corroborate the analysis of variance results for the data in Figure 3. In the assign-pro conditions, persuasiveness ratings did not correlate significantly with the writer's attitude or freedom ratings, whereas these correlations were somewhat higher in the assign-anti conditions. This suggests, as noted above, that writers in the assign-anti condition who were in favor of affirmative action wrote somewhat less persuasive essays. Finally, the correlations involving the two judgments made by observers —attitude attributions and persuasiveness ratings—were highly significant. The extremity or polarity of attitude attributions, that is, their degree of correspondent inference, related strongly to the perceived persuasiveness of the essays.

Discussion

Actors, in the role of essay writers, predicted that observers would attribute attitudes using the content of the essays—a pattern resembling that of observer data found in many previous experiments and in the present one as well. Even genuinely constrained actors estimated that observers would attach informational value to their essays, although these predictions were less extreme in the direction of essay assignment. Perhaps subjects under high constraint wrote, or felt that they wrote, less persuasive essays. The persuasiveness ratings do not suggest that this was a major factor, although the possibility exists, to a degree, for the anti affirmative action essays. Writers assigned to write against their own beliefs may have expected observers to be

Table 1
Correlations in Experimental Conditions

Item	Observer not informed		Observer informed	
	Assign anti	Assign pro	Assign anti	Assign pro
Observers' attribution and writer's attitude on essay topic	.12	−.19	.44**	$.49_a$**

**$p < .01$.

insightful regarding their constraint. However, this expectation of empathy or accuracy on the part of observers was unwarranted, because observers were completely unresponsive to the constraint variations that actually existed in the assign conditions unless they were specifically informed of the writer's self-rating of constraint.

The present results provide further evidence that perceivers' attributions—or, in this instance, actors' predictions about them—do not accord with the hypotheses derived from correspondent inference theory—a theory that calls for an estimation of the average or modal attitude in the no-choice conditions (Jones & McGillis, 1976, p. 405). The phrase *observer error* or *bias* has been used to describe these results because the perceiver does not appear to appreciate the full implications of randomly assigning the essay position to the writer—that is, the inherent lack of a systematic match between the writer's personal view and the position assigned to him. The constrained actor is conceptually in a particularly ideal position to predict the "correct" (i.e., noncorrespondent) attribution because, relative to the observer, the actor is informationally enriched. The results supported this line of reasoning to a degree, in that actors under low freedom did predict less correspondent attributions. Even these subjects, however, predicted attributions that related to the essay content. It would seem, moreover, equally "unjustified" for subjects in the high-freedom category to predict such extremely correspondent attributions of attitude. There was no logical reason for these actors under high freedom (in the observer-not-informed conditions) to expect that observers would know that they were, in fact, under such minimal constraint. What might account for this persistent tendency to base attributions on essay content and to expect others also to produce such judgments?

Research in a different but related area of attribution theory may be helpful in understanding the basis of the present findings. A number of experiments have addressed the issue of the use of consensus information in the context of Kelley's theory (1967). At issue, specifically, is the tendency for subjects to fail to use such information in a theoretically proper way. The reasons for this particular kind of attribution error are themselves complex. Some have suggested that consensus (i.e., base-rate or normative) information is pallid and abstract vis-à-vis the concrete realism of the behavior per se (Borgida & Nisbett,

1977). Others have reasoned that many research paradigms unwittingly capitalize upon subjects' lack of an intuitive grasp of the meaning of random assignment (Wells & Harvey, 1977). The attitude attribution paradigm would seem vulnerable to the same lines of reasoning. The essay itself, in terms of occupying the perceivers' time and attention, is vivid in comparison to the brief, relatively subtle impact of the no-choice instructions. Furthermore, discounting of the behavior under no-choice instructions requires that subjects understand explicitly the statistical or probabilistic implications of the essay position being randomly assigned to the writer. In this context, Wells and Harvey (1977) obtained judgments that were more in line with theoretical predictions from a group of subjects who were indoctrinated as to the meaning of random assignment. It would seem that, at the least, a manipulation of this magnitude would be required to produce similar means in the assign-pro and assign-anti conditions of the attitude attribution paradigm. To designate what subjects produce in these experiments as "error" or "bias" may, in this view, be questionable. The paradigm requires that the subject attend to an essay and make a difficult attributional response. A model ultimately stipulating that the essay should be totally discounted may itself be committing an "error of implausibility." The fact that attitude attributions are often significantly less correspondent in the assign conditions than in the choice conditions may be more of a judgmental triumph or accomplishment than has generally been acknowledged.

Another interpretation of these findings focuses not on what subjects err in doing or fail to accomplish but instead on the active, cognitive strategies that they bring to their task in this paradigm. A clue to one such strategy may be found in the matter of essay persuasiveness. Mean ratings were generally in the 5–6 range, that is, better than average, although they were based on essays assigned to writers. Actors may have been able to write better essays than they expected to be able to write, particularly when the assignment was not in line with their own attitude. Having written such essays, they may have suspected that observers would also consider the essays to be better than one might expect from someone assigned to defend a position uncongenial to his or her personal belief.

In the essay task, therefore, people may give themselves less than due credit for the ability to produce a noncorrespondent essay. They are better able to comply with the experimenter's assignment than they expect. The essays are then written in a modal range of "average to good." The attributor, however, is still operating on the premise that people assigned a position will do a poor job unless they happen to agree with the assignment. Attributions of attitude in the form of essay-correspondent judgments—what Ross (1977) and Jones (1979) term the "fundamental attribution error"—are, in this view, the logical judgment to make, but for the wrong (a priori) reasons. That is, given the strategy of basing the extremity of one's attribution on perceived persuasiveness, it is logical to attribute attitudes that are, to a degree, in line with the essays—many of the essays *are,* in fact, reasonably persuasive. The error lies in not recognizing that many writers are capable of producing respectable essays even if they personally disagree with what they are writing. There is limited but suggestive support for this line of reasoning. Jones, Worchel, Goethals, and Grumet (1971) included the important variation of presenting *strong or weak* essays to perceivers. Subjects presented with weak essays written under no-choice instructions actually attributed attitudes in opposition to the essay assignment. That is, the pattern of attributions correspondent with essay direction was not only not present but was reversed. In terms of the present line of reasoning, the persuasiveness of the weak (ambivalent) essays in the Jones et al. study may have been less than that expected by perceivers. They then inferred that the writer did not personally endorse the assigned position but in fact believed in the opposite position.

If we consider the many replications of the observer bias phenomenon in attitude attribution (Jones, 1979), the hypothesis that per-

ceivers may consistently be observing essays "better than expected" may be shown to have considerable explanatory power. An important research question involves documenting the expectancy that perceivers entertain regarding the relationship between a person's attitude and the quality of essay that the person is likely to produce. Observers in the present study produced attributions of attitude and ratings of persuasiveness that were highly correlated (Table 1). The causal direction is unclear, although on the basis of the experimental manipulations in the Jones et al. study, it could be assumed that the persuasiveness of the essay was assessed first and provided a rationale for the extremity or correspondence of the attitude attributed to the writer. Thus, the attitude–persuasiveness link appears to be an important element in the perceiver's implicit theory. A demonstrably weak or ambivalent essay would in this view be a much sounder reason for discounting the essay than the probabilistic or statistical implications of no-choice instructions.

Regarding the writer's self-rated freedom, actors, in their predictions, and observers both appeared to use this information to its fullest significance. While previous research in attitude attribution has not used this method of conveying constraint—that is, from the actor's definition of the situation—it is unclear that such a mode of transmitting the constraint or situational information is ill-conceived or beyond the province of theory. This information could, in principle, be underplayed or discounted, just as is the experimenter's instruction of no-choice to the essay writer. One need only remember that jurors found Patricia Hearst guilty despite her low degree of "self-rated freedom." Many professors have looked skeptically at students who mentioned situational causes for missing exams. In the present study, however, the actor's designation of his or her degree of constraint was information of considerable utility. Ratings of low freedom gave perceivers a salient and plausible reason for discounting the observed behavior as indicative of the writer's personal attitude. Actors expected observers to use the information in this way (Figures 1 and 2), and observers did in fact use it (Figure 3).

Inducing Biased Scanning in a Group Setting to Change Attitudes Toward Bilingualism and Capital Punishment

Patrick O'Neill and Diane E. Levings
Acadia University, Wolfville, Canada

Triads of male and female Canadian high school students were assigned to debate either capital punishment or bilingualism. Teams were given 40 minutes to prepare their arguments. Half were told in advance which side of the argument they would be debating, and half were told they would be assigned at the end of their discussion. Scoring of the taped discussions confirmed that this manipulation produced biased scanning of arguments in the predetermined condition and unbiased scanning in the later-determined condition. A postmeasure of attitudes was administered either before or after the actual debate. Biased scanning led to significant attitude change in the predicted direction, and this effect was not influenced by time of presentation of the posttest. The study provides support for the conflict theory of attitude change.

According to conflict theory as articulated by Janis and Mann (1968), attitude change is facilitated by inducing an individual to think of arguments in favor of only one side of a controversial topic. This "biased scanning" makes a set of cognitions salient and tends to shift the subject's attitude toward the position for which he or she has been developing arguments.

Girodo and Strickland (1974) suggested that the conflict theory explanation of attitude change would hold when there was high interest in the issue, when there was opportunity for the subject to think up arguments (i.e., to engage in biased scanning), and when there was incentive for the subject to do so. In their research, the largest change was produced under such conditions. It is assumed that when subjects have high interest in an issue they will have given it some thought in the past, and ideas about the issue will be stored in memory and available for scanning.

The present study attempted to test predictions from conflict theory with two issues that were expected to engage the interest of Canadian high school students: bilingualism and capital punishment. In Canada, as in a number of other countries, there is strong sentiment on the issue of the death penalty (Allmand, 1976; Fattah, 1976). Each new sensational murder revives the arguments for and against executions. The fact that Canadian legislators recently abolished capital punishment at a time when voter sentiment was strongly in favor of retention (Fattah, 1976) helps keep the debate alive.

Bilingualism is as controversial as capital punishment and more personally involves most Canadians. In response to pressures dividing the country, the federal government has actively promoted a policy of bilingualism. A much-disputed aspect of this policy is the attempt to expand the use of the French language in traditionally English-speaking areas. This has often produced a backlash from Anglophones—an outbreak of strong ethnic prejudice against Francophone Canadians. Such a situation occurred in the 1970s in the Annapolis Valley of Nova Scotia, where the Anglophone majority actively opposed the federal government's plan to move a Francophone unit to the local military base. Nova Scotia

newspapers reported that such an event would lead to "social deterioration" and warned that it was unsafe to bring Francophones into the area. A Conservative member of Parliament suggested that emotionalism was running so high that it might get out of hand. The French-speaking minority in the area, descendants of the early Acadian settlers in North America, noted with alarm that "the hate and bigotry, for so long dormant" among local Anglophones, was now apparent. The present study was done in the two Anglophone high schools closest to the site of the proposed Francophone "invasion," where it was anticipated that students' feeling of involvement with the issue would be very high.

Laboratory studies of attitudes, including the conflict theory of attitude change, are typically done with individuals rather than groups. However, the use of groups has several advantages. First, in our society many decisions are made, issues are considered, and biased scanning of information often occurs in a group context. Therefore, it is of some interest to know whether the results of studies with individuals generalize to group situations. Second, if a group is induced to discuss an issue, the discussion can be recorded so that biased or unbiased scanning of arguments can be measured directly rather than being merely inferred.

Several studies have used techniques in which subjects generate arguments on one side of an issue because they must defend that position in a debate (Scott, 1957, 1959; Hilchey & O'Neill, Note 1). In the present study, triads of high school students discussed either capital punishment or bilingualism in preparation for a debate on the topic with another "team." The involvement value of these issues has already been noted. Students were also offered incentives in the form of cash prizes for winning teams and further cash awards as grand prizes. The purpose of the study was to compare biased versus unbiased scanning of arguments directly to determine whether attitude change would be a function of biased scanning. Half of the subjects were told before their preparation session which side of the issue they would debate, and half were not assigned until after their preparation session. It was anticipated that the former condition would lead to relatively more biased scanning of arguments and consequently to more attitude change.

It might be argued that while biased scanning produces more attitude change initially, such persuasive effects fade away when exposed to counterarguments. This might be the case, because if biased scanning is employed, the subject is not innoculated against arguments on the other side of the issue (McGuire & Papageorgis, 1971). To check this possibility, for half of the subjects the postmeasure was given following the preparation session and before the debate. For the other subjects the postmeasure was given following the debate, when those in the biased scanning condition would have been faced with counterarguments that they had not considered.

Because no pretest was used in the present study to minimize reactivity (Campbell, 1969; Campbell & Stanley, 1966), it may be useful to comment on the initial positions of the subjects that can be deduced without a premeasure. As indicated, ethnic prejudice against French Canadians was running high in the target area at the time of the study. On capital punishment, Hilchey (Note 2) reviewed evidence to indicate that Canadians in general and Nova Scotians in particular tend to be in favor of the death penalty. She found, in a university near the site of the present research, that students were overwhelmingly in favor of capital punishment. It might be assumed that this was also the general sentiment of the high school population from which our sample was drawn.

Pretest of the Instrument

Before running the present study, a postmeasure of attitude change was designed specifically to focus on the issues of bilingualism and capital punishment. A disguised technique similar to Cook's measure of plausibility (Brigham & Cook, 1970; Waly & Cook, 1965) was used. Subjects were asked to "rate how convincing these arguments are; circle the appropriate number after each argument." The numbers ranged from 1 (not convincing) to 7 (very convincing) with no other labels.

There were 13 arguments. Only 8 were scored in this study, 4 on the bilingualism issue and 4 on capital punishment; the other arguments were on women's liberation and were "fillers." On each issue, two arguments supported one side and two supported the other. The following are examples of arguments about capital punishment:

If a person is executed for murder, we can be absolutely certain that he will not kill again. Any other sentence always leaves open the possibility that an appeal board will mistakenly free a dangerous killer, or that he may escape from prison. In cases where guilt is beyond doubt, dangerous murderers should be given the death penalty.

Many jurors are extremely reluctant to convict when the death penalty may be the result. There would certainly be more convictions if juries knew that life imprisonment was the most serious penalty that could be applied. It is better for law and order to have two murderers convicted and sent to prison than to have one convicted and executed and the other set free. Therefore, capital punishment should be abolished.

The following are 2 examples of arguments on the bilingualism issue:

People of many races, cultures and languages have played their part in the development of Canada. This is not just a country of English and French. It makes as much sense to say that we should all speek Cree and Inuit, Greek and Italian, as to say that we should all speak French and English. To expect that all Canadians will be fluent in more than their own language is simply impractical.

Canadians must deal with the fact that there are two major languages in the country. Each language is spoken by so many people that this can never be a country where everyone speaks one language, like the United States. If the country is to remain united, both major groups must make an effort to understand and communicate with one another; to do that, they must overcome the language barrier.

This measure[1] was pretested on university students in introductory psychology classes. They were given the questionnaire while being told that the experimenter planned to do research on debating and needed to know how "convincing" these arguments seemed. Scores on items were added to get separate totals on the capital punishment and bilingualism issues. Two months later, a different experimenter telephoned students who had scored highest or lowest on each of the issues. There were 10 high and 10 low on each issue. Students came to the laboratory individually. They were told that for some future research we needed to develop a number of arguments on current affairs topics. Topics assigned were feminism and either capital punishment or bilingualism. For the two target issues, the statements were (a) "We need to bring back capital punishment to lower the crime rate in Canada" and (b) "All Canadians should learn to speak both French and English to make the country fully bilingual."

Table 1
Distributions of Validation Subjects on the Questionnaire and Side Chosen in Writing an Essay

Essay	Questionnaire: In favor	Questionnaire: Against
Capital punishment issue		
In favor	8	2
Against	0	10
Bilingualism issue		
In favor	9	1
Against	0	10

The students were told that they should take one side of the issue and write an essay containing as many arguments as they wished. They were told, "It doesn't matter to us which side of the argument you pick; it's probably going to be easier if you pick the one you agree with." Of course, the side picked was exactly what interested us. Students in this validation study could be classified as in favor of or against capital punishment or bilingualism on the basis of scores on the target instrument and again on the basis of the side they chose when writing an essay 2 months later. The results are presented in Table 1. They are in the predicted direction for both issues, significant beyond the .005 level using the Fisher's exact test. The reliability of the measure was estimated using the Spearman-Brown formula. On the pretest, the reliability was .48 for the bilingualism ques-

[1] Copies of the instrument are available on request from the first author.

tions and .71 for capital punishment. In the main study the reliability was .40 for bilingualism and .64 for capital punishment.

Method

Subjects

The study involved 48 students, 24 males and 24 females, from two high schools, all from Grades 11 and 12.

Procedure

First contact with subjects was made in their classrooms, where they were told that they would be invited to take part in research on debating, that no previous experience in debating was necessary, that participation was voluntary, and that cash prizes of $5 would be given to each person on the winning side in a debate, with an additional $25 given to the three best debaters in each school. The night before each session, six males or six females were chosen at random from class lists and were telephoned, invited to take part, and given a time and place. If a student was not available, same-gender replacements were taken randomly from class lists.

Sessions were held immediately after school hours in two classrooms. When the six students arrived, they were met by two experimenters. Subjects were divided into triads alphabetically according to the first letter of the last name. Each experimenter then took three subjects to each of the rooms. The following instructions were given to the assignment-before-discussion group:

> As you know, we are doing research on debating. The procedure is not very complicated. You will be assigned a current affairs topic (and you will be told which side of the issue to debate). You will have 40 minutes to discuss the topic and consider what arguments you might present. As you know, another group is meeting in another room to discuss the same question (and they will be assigned the other side of the issue). At the end of the 40-minute discussion we will bring the two groups together for the actual debate.

The modifications in instructions made for the assignment-after-discussion condition were the omission of the phrases in parentheses and the insertion of the sentence "At the end of the discussion I will tell you which side of the issue you must present in the debate; of course the other group will be assigned to the other side of the issue." They were told that the debates would be taped and would later be evaluated by two judges at the university to determine the cash awards. Subjects were then told:

> We will also be taping your discussion now, before the debate—but that's just for our own records. The judges will *not* hear it, and of course it will have no bearing on whether you win or lose.

In the assignment-before condition, subjects were informed:

> I'll give you a slip of paper telling you what topic you are to debate and which side you are on. This has been determined randomly. Here is your topic.

The experimenter then opened a sealed envelope and handed a slip of paper to a member of the group. This slip provided both the statement of the issue and the position (in favor or against). The procedure was similar for the assignment-after condition, except that only the issue—and not the side to be debated—was given before the discussion. The issues stated were (a). "We need to bring back capital punishment to lower the crime rate in Canada and (b) "All Canadians should learn to speak both French and English to make the country fully bilingual." The discussions were taped on cassette tape recorders using small omnidirectional lapel microphones that were hung from the ceiling.

At the end of the discussion period, the posttest was administered to half of the triads. In each room, the experimenters told their groups:

> While we're waiting, I'd like to get you to do a small task for me. This will help us with another research project. We have a number of different current affairs topics, and we're not sure how convincing certain arguments are about those topics. I'd like you to help by reading over these arguments, one at a time, and rating them to indicate how convincing they are. We'll use the arguments that are judged most convincing and discard the others.

After this the two triads were brought together, and the debate took place. Each debater was given 5 minutes for initial presentation of argument, with speakers from each side alternating. Then each side had another 5 minutes for rebuttal. For half of the groups the posttest was administered following the debate, using instructions similar to those above.

Design

To determine whether time of assignment was successful in producing biased versus unbiased scanning, each triad was treated as a subject in a 2×2 factorial, with time of assignment as one factor (before or after the predebate discussion) and issue as the second factor (capital punishment or bilingualism). Testing for attitude change effects, with each individual now constituting a subject, another 2×2 factorial was employed with time of assignment as one factor and time of administration of the attitude measure as the second factor (before or after the debate.[2]

[2] It will be noted that in the attitude change portion of the study, "issue" was not used as a factor but was counterbalanced within conditions. In the

Results

There were three major questions of interest in the present study.

1. Were we successful in producing biased versus unbiased scanning in the assignment conditions?

2. If so, did biased scanning lead to more attitude change?

3. If so, was this attitude change affected by the time of presentation of the posttest (i.e., before or after the debate)?

Biased Versus Unbiased Scanning

Each 40-minute tape was scored by one of four experienced raters who had been trained in a previous study that used the same scoring procedure (Hilchey & O'Neill, Note 1). Each time an argument was raised in group discussion, the rater briefly noted the content of the argument and indicated whether it was for or against the issue. In cases where there was doubt, one of the other raters would be consulted for a second opinion. The definition of an argument, taken from Fowler and Fowler (1969), was "a reason advanced for or against." Examples of statements not counted as arguments included "I'm against capital punishment" and "we studied capital punishment in Grade 10." Generally, however, the concept of an argument was interpreted liberally, with any reason given for or against a position being scored. Each time an argument was advanced, it was counted. Thus, for example, a group member might say "bilingualism will unite our country" several times during the discussion, and this would be noted as a probilingualism argument each time it was raised. The quality of the arguments was not an issue, merely the extent to which the group considered one side or both sides of the question. When the tapes were scored, a ratio of pro and anti arguments was computed, varying between 0 and 1, with 1 indicating a perfect balance and lower numbers indicating a tendency to focus on only one side of the issue. Mean scores for the assignment-before-discussion condition were bilingualism issue = .19, capital punishment issue = .11; for the assignment-after condition, mean scores were bilingualism issue = .55, capital punishment issue = .87. In a 2×2 analysis of variance, looking at time of assignment and issue, there was a main effect for time of assignment, $F(1, 12) = 124.0$, $p < .001$, with the assignment-before condition producing more biased scanning; there was a main effect for issue, $F(1, 12) = 6.0$, $p < .05$, but this effect can best be explained in terms of the significant interaction between issue and time of assignment, $F(1, 12) = 17.0$, $p < .005$. When subjects did not know which side of the issue they would be required to argue, they were much more unbiased in their consideration of capital punishment than they were in their consideration of bilingualism. This effect was substantiated by the Newman-Keuls procedure, which showed a significantly higher score (more unbiased discussion) for capital punishment than for bilingualism within the assignment-after condition.

Attitude Change

Because we were successful in producing biased scanning, it was expected that there would be more attitude change in the biased scanning (assignment-before) condition. A possible confounding variable was the actual

---

usual laboratory study of persuasion, where issues have less social impact, a design including issue as a factor would typically be employed even when this factor is expected to have no effect. In the present study, however, ethical concerns prevented us from employing the assignment-before condition, which we expected to produce the most attitude change, to increase ethnic prejudice. The assignment-before condition was therefore always used for the "in favor" side on bilingualism and the "against" side on capital punishment. Because the assignment-after condiiton should not produce biased scanning and thus should have less impact on attitudes, this condition was used for the antibilingualism and the procapital punishment sides. This permitted a procedure where triads could be assigned to each side of the issue, and following their separate discussions they could be brought together for a debate. In summary, each cell of the second 2×2 factorial contains an equal number of males and females, an equal number arguing in favor and against an issue, and an equal number discussing bilingualism and capital punishment.

Table 2
Mean Scores on the Posttest for Assignment to Discussion and Time of Attitude Measurement

Issue	Assignment before discussion (biased scanning)		Assignment after discussion (unbiased scanning)	
	Attitude measure		Attitude measure	
	Before debate	After debate	Before debate	After debate
Bilingualism	5.25	4.79	4.29	3.92
Capital punishment	4.79	5.25	3.98	3.71
M	5.02	5.02	4.14	3.81

Note. Attitude posttest was scored in the direction of assignment.

direction of assignment, which was expected to have an effect itself. This was controlled by scoring the posttest in the direction of assignment. Thus, the mean score on the 7-point scale indicated amount of agreement with either the "in favor" position or the "against" position, whichever was assigned. Mean scores on the postmeasure are presented in Table 2. Each cell included an equal number of males and females, an equal number debating in favor and against, and an equal number debating bilingualism or capital punishment. There was a significant main effect for time of assignment, $F(1, 40) = 21.01$, $p < .001$, with biased scanning producing more attitude change. Neither the main effect of time of attitude measurement nor the interaction was significant, indicating that the persuasive effects of biased scanning were not affected by listening to opposing arguments during the debate. The analysis of group discussion indicated that in the assignment-after-discussion condition, discussion was somewhat more unbiased on the capital punishment issue than on bilingualism, and in view of this fact similar differences in attitude change might be expected. Table 2 indicates that there was a trend in this direction, although it was nonsignificant.

Discussion

Conflict theory suggests that when a person is induced to think of arguments for only one side of an issue, those arguments become salient and influence attitudes. The theory previously received support in studies with subjects run individually. The present research indicates that the effect can be produced in a small group setting.

An advantage of using groups and recording group discussion is that biased or unbiased scanning of arguments is made public; researchers can hear and score arguments and quantify the degree of bias toward one side or the other. In studies with individuals, the experimenter is typically left in the position of inferring that biased scanning has taken place, reasoning backward from the results (e.g., Girodo & Strickland, 1974). An obvious disadvantage in the use of groups is the lack of control over all the factors that influence attitude change. We cannot be sure to what extent a subject is changing his or her attitude as a function of self-generated arguments or because he or she hears persuasive arguments from others in the group. Indeed, these factors may interact so that potential debaters are more receptive to one-sided communications from others (see Greenwald, 1969, 1970). While such questions cannot be answered in an experiment such as the present one, these factors were not the focus of the research and would have no systematic influence on the results.

Half of the subjects were not given the postmeasure until after they had debated the issue and had heard counterarguments. It is known that subjects can be "immunized" against counterarguments by hearing them in

mild form before such arguments are presented with persuasive intent (McGuire & Papageorgis, 1961). In this study, however, the attitude change created by biased scanning was not affected by the time of the posttest. Still, caution should be used in generalizing this result beyond the present experimental procedure. There may be some aspects of debating per se, including the competitive aspects involved and the probable arousal of reactance (Brehm, 1966), that make counterarguments presented during a debate ineffective in persuading the opposing side.

An unexpected finding was the interaction between issue and time-of-assignment in producing biased scanning. For both issues, groups that had to prepare for the debate without knowing their eventual assignment were much more unbiased in their consideration of arguments than were groups in the assignment-before condition. But within the unbiased condition, subjects were significantly more balanced in their treatment of capital punishment than bilingualism. This study was done in a geographic area where bilingualism is a matter of considerable debate and concern; presumably capital punishment, however interesting it might be to the subjects, touched few of them directly. This provides a footnote to the point made by Girodo and Strickland (1974) that "high interest" in an issue promotes biased scanning and facilitates attitude change. It seems that high interest in the sense of personal involvement with an issue also makes it more difficult to create *unbiased* scanning of arguments, even when there is high incentive to look at both sides of the question.

Editors Named for New *Journal of Personality and Social Psychology*

The Publications and Communications Board has named Melvin Manis, Ivan D. Steiner, and Robert Hogan to edit the *Journal of Personality and Social Psychology* (JPSP), which will appear in a new format in 1980. The affiliations of the new editors are, respectively, University of Michigan and Veteran's Hospital, Ann Arbor; University of Massachusetts; and Johns Hopkins University. Manis will edit the section on ATTITUDES AND SOCIAL COGNITION, Steiner the section on INTERPERSONAL RELATIONS AND GROUP PROCESSES, and Hogan the section on PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES.

An announcement on the restructuring of JPSP appeared on p. 668 of the June 1978 issue of JPSP. As indicated at that time, the three editors will work independently with separate groups of advisory editors. Their acceptances will appear as distinct sections in monthly issues of JPSP. Detailed descriptions of each section's coverage appear on pages 468–469 of the March issue of JPSP.

Authors should submit manuscripts to the appropriate section editor as follows:

ATTITUDES AND SOCIAL COGNITION

Melvin Manis
Research Center for Group Dynamics
Institute for Social Research
University of Michigan
Ann Arbor, Michigan 48106

INTERPERSONAL RELATIONS AND GROUP PROCESSES

Washington, D.C. 20016

The Journal Supplement Abstract Service is an information service providing ready access to psychology-related materials not available through conventional communication channels.

JSAS Selects and Disseminates:

- Educational materials
- Massive data collections
- Methodological techniques and procedures
- Major projects in progress
- Descriptions of effective techniques or programs
- Technical reports
- Fresh looks at controversial issues
- Invited lectures
- Management of psychological resources
- APA task force reports
- Bibliographies
- Literature reviews

Manuscripts are accepted by a panel of editors. They meet the same high standards set for American Psychological Association's journals, but are not bound by conventional restrictions of format, length, or editorial policy.

Available titles are listed in the quarterly JSAS *Catalog of Selected Documents in Psychology.* The catalog includes abstracts of newly accepted manuscripts along with manuscript length, price, and ordering information. Each issue of the catalog contains about 50 abstracts. Full-text manuscripts may be purchased individually in paper or microfiche.

Subscription rates for the quarterly catalog are $6 for APA members and $14 for nonmembers (foreign, $16). Please include full remittance for orders of $25 or less. To order, make check payable to APA and mail to:

The Journal of Personality and Social Psychology publishes original reports of research, methodology, theory, criticism, and literature review in the fields of personality and social psychology of normal processes and populations. Submitted manuscripts should delineate an important question and provide a clear answer to it. In the case of research reports, this will often require demonstration that the reported results are generalizable beyond a single research setting. Consult the editorial in the January 1976 issue (Vol. 33, pp. 1–7) for a detailed statement of policies and instructions to authors.

Manuscripts: Submit manuscripts in quadruplicate, prepared according to the *Publication Manual of the American Psychological Association* (2nd ed.). Copies should be highly legible and will not be returned to authors unless they are original typewritten copies. Mail manuscripts according to instructions on p. 1439 of the August issue.

Required supplementary information: Manuscripts cannot be reviewed for publication unless the author provides supplementary information in the following categories: (a) a cover letter that indicates the relation (or the lack of relation) of the submitted manuscript to other papers by the same author(s) that are currently submitted, in press, or recently published; (b) one copy of each such related paper; (c) one copy of a statement of the procedures of the research reported in the submitted manuscript in sufficient detail to serve as a guide for conduct of an exact replication; and (d) one copy of the summary tables (e.g., correlation tables, analysis of variance summaries) for the *major* analyses reported. If it appears that the supplementary materials in categories (c) or (d) might be bulky, the author should exercise judgment and restraint in selecting what to send. It is not necessary to send supplementary material that repeats verbatim manuscript content.

After a manuscript is accepted, authors will be expected to provide assurance that their data are available in unanalyzed form for reanalyses by other investigators and that their research procedures were consistent with the American Psychological Association's published principles of research ethics, except insofar as may be detailed otherwise in the manuscript.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permission is normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of $10 per page, table, or figure. Abstracting is permitted with credit to the source. Permissions and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Permission and fees are waived for the photocopying of isolated articles for nonprofit classroom or library reserve use by instructors and educational institutions. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles with a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301. Address requests for reprint permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $60 domestic, $64 foreign, $6 single issue. APA member rate: $20. Write to Subscription Section, APA.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Published monthly in one volume per year by the American Psychological Association, Inc., 1400 North Uhle Street, Arlington, Virginia 22201. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

On Problems With the Cause–Reason Distinction in Attribution Theory

John H. Harvey and Jalie A. Tucker
Vanderbilt University

Buss's statement on causal and reason explanations of behavior involves a contribution regarding a necessary distinction in attribution theory. In this paper, we argue that despite his ambitious reformulation of previous analyses of lay attribution, Buss fails to provide substantive guidance for empirically testing the major assumptions of his hypothesized cause–reason distinction. Most important, Buss's analysis does not yield unambiguous theoretical criteria for operationally distinguishing intentional actions and unintentional occurrences and for judging the content of actors' and observers' explanations as causal or reason in nature. Without such specifications, we conclude that Buss' central ideas may be empirically untestable.

> We are now in a position to . . . steer a truer course that will lead us out of the conceptual fog with regard to causes and reasons in the attribution process. (Buss, 1978, pp. 1319–1320)

When a theorist makes such an assertion, however metaphorical, about integral concepts in a domain of work, that theorist's ideas invite and deserve careful scrutiny. In this paper, we seek to provide such scrutiny of the major aspects of Buss's (1978) reconceptualization of previous attributional analyses of lay explanation of behavior.

We are indebted to Gary Wells for comments on an earlier version of this paper.

Requests for reprints should be sent to John H. Harvey, Department of Psychology, Vanderbilt University, Nashville, Tennessee 37240.

To summarize Buss's position, he argued that attribution theorists (e.g., Heider, 1958; Jones & Nisbett, 1972) have failed to distinguish both conceptually and empirically between two logically distinct types of lay explanation (i.e., causal and reason explanations) and that this lack of distinction has greatly impeded an accurate understanding of this major area of social psychological inquiry. As an alternative to previous attributional analyses of lay explanation (especially the Jones & Nisbett, 1972, actor–observer hypothesis), which he considered exclusively causal in nature, Buss proposed (a) that an actor's behavior may be dichotomized according to whether it was intentionally or unintentionally initiated (termed an "action" and an "occurrence," respectively) and (b) that actors and

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3709-1441$00.75

observers differ in the types of explanations they may give for actions and occurrences. More specifically, Buss hypothesized that occurrences were explained exclusively with causes by both actors and observers and that actions were explained solely with reasons by actors, whereas observers could give reason or causal explanations of actions.

We readily acknowledge the potentially important contribution of Buss's statement in making this conceptual distinction between causal and reason explanations of actions and occurrences. However, although Buss is correct in concluding that this distinction has not been *formally* addressed in relevant attribution writings, his assertion that theorists have uniformly neglected reason explanations in favor of a causal analysis represents an overly generalized, polemical criticism. For example, see Heider (1958, p. 100) and Jones and Davis (1965, pp. 222, 263) for prior discussions of the role of reason explanations and actor intentionality in lay attributions. More importantly, we find Buss's statement most problematic in terms of its cogency and clarity as a reformulation of actor–observer phenomena. It will be argued below that while Buss's position may eventually contribute to a better understanding of lay explanations of behavior, ambiguities and oversights inherent in his analysis, especially in relation to the empirical testability of his ideas, greatly reduce the potential importance of his conceptualization.

Issues Involved in an Empirical Separation of Actions and Occurrences

Fundamental to Buss's conceptual distinction between causal and reason explanations is an assumption that an actor's behavior can be unambiguously dichotomized as either intentional action or unintentional occurrence. Thus, an adequate empirical test of Buss's hypothesized cause–reason attributional distinction rests on the operational separation of actions and occurrences, which he perceives as having generally been confounded in earlier research on actor–observer differences. As detailed below, we maintain that Buss's statement does not provide either a clear logical or empirical basis for operationalizing actions and occurrences.

In an attempt to clarify the nature of this error in previous research, and to illustrate his definitions of actions as consciously controlled intentional behaviors and occurrences as unwilled behaviors that the actor "suffers," Buss cited a number of examples of actions and occurrences from relevant experimental work. Examples of actions were intelligence test performance, expression of attitudes and opinions, translation of sentences, decision behavior, and carrying parcels (p. 1318); examples of occurrences were headache, blushing, perspiring, emotional arousal, galvanic skin response, friendliness, talkativeness, nervousness, dominance, and looking happy (pp. 1317–1318). Unfortunately, for an investigator seeking operational definitions of actions and occurrences, the criteria implied by these examples for distinguishing the two types of behavior present substantial difficulties. First, Buss's examples imply that physiological responses and overt displays of emotion are occurrences that operate completely outside the actor's conscious control, while actions encompass all deliberate behaviors, including those dependent on innate abilities such as intelligence. On both logical and empirical grounds, one must seriously question the implicit assumptions (a) that physiological responses and overt manifestations of emotionality cannot be at least partially controlled consciously (cf. Miller, 1969) and (b) that behaviors dependent on innate abilities can be completely controlled and deliberately manipulated (cf. Kruglanski, 1975).

Similarly, Buss's classification of the expression of attitudes and opinions as intentional actions is questionable on the grounds that attitude expressions are often affected by various experimental manipulations and/or self-perception processes (Bem, 1972) that do not appear to be readily controllable by the actor; thus in these instances it may be argued that the expression of an attitude represents an occurrence, not an action, in Buss's scheme. When one further considers that Buss classified expression of opinions as an action but regarded "looking happy" as an occurrence, one is left with the curious conclusion that if we say we like someone (an opinion), it is an intentional action; but if we smile in the

resence of this same person ("look happy"), is an unwilled occurrence. Although these ssues raised as a result of Buss's examples are robably not fundamentally damaging to his asic action–occurrence distinction, they evertheless demonstrate the difficulty in lassifying behaviors according to the actor's apacity to control various behaviors inten- ionally and consciously.

A second, highly related issue in determin- ng whether an actor's behavior should be lassified as an action or an occurrence con- erns specification of criteria for imputing ntention to an actor's behavior in ambiguous ituations where the behavior in question may r may not have been controlled by the actor (e.g., as in the case of overt displays of emo- ion). Despite Buss's contention that inten- ionality is a crucial differentiator of actions and occurrences, he did not address potential problems in imputing intentionality, thereby implying that it is usually possible to establish clearly whether or not an actor's behavior is intentional. One can envision ambiguous circumstances, however, where the actor, observer, and investigator fail to agree on the presence or absence of the actor's intentionality and/or conscious control over a given behavioral sequence. To use Buss's example (pp. 1317–1318) of such a situation, the experiments by Storms (1973), Regan and Totten (1975), and Taylor and Fiske (1975) involved actors and observers giving explanations of the actor's degree of friendliness, talkativeness, nervousness, and dominance in a "getting acquainted" situation. On the one hand, Buss classified these behavioral dimensions as occurrences that should evoke causal explanations from both actors and observers. Buss also allowed, however, that if the actor consciously controls his/her self-presentation along these dimensions, the actor would provide a reason, rather than a causal, explanation of behavior. Alternatively, the actor might adamantly deny any such willful manipulations, whereas the observer and investigator might perceive the actor as consciously and intentionally controlling his/her behavior.

In light of potential disagreements between the actor, observer, and investigator concerning the presence or absence of intention on the actor's part, the investigator would seemingly be forced either (a) to rely on the actor's self-report of his/her behavioral intentionality or lack thereof or (b) to judge the content of the actor's explanation to determine whether it comprises a reason or causal explanation of an intended action or unintended occurrence, respectively. The first possibility depends on the somewhat questionable validity of the actor's self-report, especially in relation to willingness and ability to admit intention, whereas the second depends on the existence of independent criteria that can be used to classify the content of explanations as either primarily causal or primarily reason in nature. As will be discussed in the following section, Buss's analysis does not readily yield such criteria.

Overall, we must conclude that Buss's analysis is weak in clarity of definitions or empirical implications for concepts such as intention and conscious control of behavior, which are central to his action–occurrence distinction. Presumably, these concepts refer to qualities of actions, not occurrences, but is it necessary for both to exist for an action to be perceived? For instance, would it not be possible for a behavior to be consciously and deliberately taken, but not intentionally initiated? Considerations such as these are totally lacking in Buss's analysis and require further explication if his statement is to be of much value to researchers.

Empirical Implications of the Cause–Reason Distinction

Buss's second major assumption, that actors and observers differ in the types of explanations they give for actions and occurrences, also entails major difficulties in its empirical implications. In line with his criticism that existing actor–observer research has typically confounded action and occurrence behaviors, Buss seems to suggest that actor–observer differences should be investigated by having actors and observers give explanations of behaviors that can unambiguously be classified as actions and occurrences. One thus can formulate a basic experimental design to test the validity of Buss's cause–reason distinction;

this design would involve comparisons of the explanations offered by actors and observers of both actions and occurrences.

Under these experimental conditions, Buss's model predicts that no differences should be expected in the content of actors' and observers' (causal) explanations of occurrences, but that differences may be expected in their explanations of actions. That is, actors may give only reason explanations for actions and observers may give reason, causal, or reason plus causal (mixed) explanations. Buss further contended that the types of explanations elicited from observers to explain actions may be manipulated by instructing the observer (a) to explain the action using reasons as he/she perceives the actor would, (b) to give a reason explanation based on the observer's personal interpretation of the action, or (c) to give a strictly causal explanation (p. 1318). Conceivably, actors could also be instructed to give explanations from the perspectives of both the self and an observer. Buss did not consider this latter possibility, however, apparently because his model precludes the possibility that actors might give causal explanations of actions by adopting the perspective of an observer. Only when both actors and observers give explanations of the same logical form (i.e., when actors and observers explain occurrences with causes and actions with reasons) did Buss consider the resulting explanations as directly comparable. Despite this assertion about the logical comparability of explanations under these conditions, Buss also maintained the seemingly inconsistent position that actors and observers "are engaged in *fundamentally* (i.e., logically) *different* situations to explain the same action" (p. 1316). Overall, it would seem that an adequate empirical test of Buss's cause–reason distinction would involve having both actors and observers explain actions and occurrences from the perspective of both an actor and an observer.

Although this experimental design seems to assess adequately the validity of Buss's cause–reason distinction, his statement is obscure regarding meaningful a priori criteria for distinguishing and classifying the content of the explanations that would be produced. For instance, Buss merely states that causal and reason explanations may be distinguished by the greater degree of justification "vis-à-vis society's norms for 'proper' conduct" (p. 1315) in reason than causal explanations, and by the greater degree of "such 'connotative attributes' as lawfulness, determinism, antecedent–consequent relationship, predictability and replicability" (p. 1314) in causal than reason explanations. He fails, however, to elaborate on how these rather vague distinctions might be measured in explanations derived in an experimental situation. This difficulty in empirically classifying explanations as causal or reason is compounded further by Buss's contention that actors give reason explanations of actions that are couched in causal terminology (pp. 1315, 1318), and that observers may make justifications for the actor (p. 1318).

It may prove possible, of course, to establish empirically those situations in which content differences in actors' and observers' explanations of actions are either maximized or minimized, in a manner similar to findings of divergence and convergence in actor–observer explanations conducted within the actor–observer research paradigm (e.g., Wells, Petty, Harkins, Kagehiro, & Harvey, 1977). Notwithstanding this possibility, however, Buss's failure to articulate well-developed a priori criteria for establishing the causal or reason nature of explanations must be considered a fundamental shortcoming of his theoretical conceptualization. Without better a priori criteria, one is generally left in the scientifically indefensible position of defining, in a circular manner, reason explanations as those given by actors for actions and causal explanations as those given by actors and observers for occurrences.

A final issue, which indirectly relates to problems in investigating Buss's conceptualization, concerns his implicit characterization of the information sources and perceptive capacities of actors and observers. Specifically, in comparison to Jones and Nisbett's hypothesis, Buss implicitly appears to accord the observer more and the actor fewer information sources and perceptive powers for deriving attributions. Whereas Jones and Nisbett em-

dasized that the actor often possesses more
levant information regarding his/her be-
avior than the observer, who often merely
impses short segments of the actor's ongoing
ehavior, Buss instead presented the observer
possessing the capacity to perceive motives
nd forces influencing the actor's behavior
at operate outside the actor's awareness (p.
316). The observer and also the investigator,
ho qualifies as an observer, may then use
is information to give a causal explanation
f the actor's behavior. In contrast, Buss de-
icted the actor's perceptual and attributional
pacities as substantially limited by his/her
eed to provide society with a justification for
ersonal behavior.[1]

Hence, in Buss's conception, the observer is
ssentially characterized as capable of omni-
iently perceiving unconscious forces influ-
ncing the actor's behavior, which form the
asis of the observer's truly causal explanation
f the actor's behavior. This implied view is
rprisingly consistent with the disinterested-
cientist efficient-causality model that Buss
eems to reject. Buss's implicit characteriza-
ion of the perceptual and attributional capac-
ies of actors and observers does not neces-
arily invalidate the basic cause–reason dis-
nction advanced in his paper. Nonetheless,
s questionable foundation, which involves
ttle consideration of extant evidence and
nalysis regarding actor–observer inference
rocesses, does lessen the intuitive appeal of
uss's conceptualization.

Conclusions

The foregoing discussion highlights some of
he issues and problems involved in attempt-
ng to incorporate Buss's ideas in empirical
nvestigations of lay explanations of behavior.
We acknowledge that his criticism regarding
he previous failure of attribution investiga-
ors to distinguish actions and occurrences em-
pirically is well taken. However, we must
onclude that Buss's analysis offers little sub-
tantive guidance in establishing theoretical
criteria for distinguishing between these two
types of behavior or in testing his hypothesis
regarding logical differences in the types of ex-
planations given by actors and observers.
Without better criteria for distinguishing actions and occurrences and for judging the content of explanations as causal or reason in nature, the impact of Buss's contribution approaches that of an untestable armchair analysis.

---

[1] Although Buss may reasonably take issue with Jones and Nisbett's assumptions about possible mediators of actor–observer differences, he fails to elaborate the psychological processes that may mediate actors' presumed preoccupation with justifying, reason explanations. If, as Buss implies, motivations associated with self-esteem maintenance or enhancement, or with self-presentation concerns, underlie actors' reason attributions, we view Buss's analysis as inadequate in its failure to address several works relevant to the role of self-serving bias mediators of attributions, such as Miller and Ross's (1975) and Bradley's (1978) influential discussions of information processing alternatives to a self-esteem position or Monson and Snyder's (1977) important reconceptualization of the psychological processes involved in actor–observer attributional phenomena.

New JPSP Format Delayed Until April

Recent issues of this journal carried an announcement that the *Journal of Personality and Social Psychology* would appear in January 1980 under new policies and in a new sectioned format. However, in order to publish the backlog of manuscripts accepted under present policies, the first three issues of 1980 will continue to carry articles accepted under Clyde Hendrick's Acting Editorship.

This journal will appear in April as a sectioned journal edited by Melvin Manis, Ivan D. Steiner, and Robert Hogan, as previously announced.

Causal Explanation, Teleological Explanation: On Radical Particularism in Attribution Theory

Arie W. Kruglanski
Tel-Aviv University, Tel-Aviv, Israel

The cause–reason distinction in attribution theory is examined. The author notes conceptual difficulties associated with previous interpretations of cause as opposed to reason and offers a reformulation that shows how *reason* may refer to a specific type of explanation (notably, teleological) and *cause* may refer (a) to the general case of explanation (the inclusive sense) *or* (b) to the general case of nonteleological explanation (the exclusive sense). From this perspective he considers Buss's recent comments regarding teleological and nonteleological (causal) modes of naive explanation. It is noted that teleological (reason-type) explanation does indeed fall within the purview of attribution theory but is merely one among a vast number of possible explanatory types that all properly belong within the attributional domain. Hence, the reason concept is of no unique significance for the theory of attribution. The foregoing argument culminates in the conclusion that a theory of naive epistemology might well rid itself of concern with lay concepts (such as cause and reason) that have figured frequently in attributional formulations. Such concepts may be thought of as the *contents* of knowledge, of which there may be an infinite variety. Instead, an epistemic theory should restrict itself to the *process* of knowledge acquisition assumed to be invariant across the diverse epistemic contents of possible interest to the layperson.

My object in the following pages is to consider the cause–reason distinction in attribution theory and to comment on Buss's (1978) recent discussion of this topic. Despite my disagreement with some of its contents, I find Buss's article of considerable interest, particularly as it calls attention to the relevance of British philosophy of the ordinary language (e.g., Anscombe, 1957; Austin, 1962; or Ryle, 1949) for contemporary research on attribution (Harvey, Ickes, & Kidd, 1976, 1978; Jones, Kanause, Kelley, Nisbett, Valins, & Weiner, 1972; Kelley, 1967).

The main task that the ordinary-language philosophy set for itself was the explication of concepts in everyday discourse. Buss (1978) takes two such concepts, cause and reason, and proclaims them of central importance to the theory of attribution. By contrast, I have felt for some time (cf. Kruglanski, 1977; Kruglanski, Hamel, Maides, & Schwartz, 1978; Kruglanski & Bar-Tal, Note 1) that the preoccupation with lay concepts threatens to ensnare attribution theory in endless particularities that might ultimately divest it of scientific value. In the remainder of this article I present my arguments for this position, with special reference to the cause–reason issue.

The present essay is composed of four major parts. In the first, some difficulties are noted with common conceptions of cause and reason, and a reinterpretation is offered clear of those difficulties. In the second part, teleological and nonteleological modes of naive explanation are examined and are contrasted with Buss's views on these matters. The third part deals with Buss's claim that conceptual confusion in attribution research may have resulted from a failure to draw the distinction between cause and reason. In the fourth part the cause–reason issue is cast into broader per-
